Recent Impressions of Urology in Europe.—The chief paper of the evening was read by Dr. Oswald Swinney Lowsley. He said that he saw three outstanding urological departments. The first described was the service of Primatorius Kroiss in Kaiserjübilaens Hospital in Vienna. It contained the best kidney operating table he had ever seen, and two cystoscopic rooms equipped with an interesting but very simple device for holding the cystoscope in position. It consisted of a fixed pulley just over the table, and a moveable one with weight attached which was just sufficient to hold the instrument. A light cord was strung through these pulleys. Another excellent service was that of Prof. Edmond Papin, in St. Joseph's Hospital in Paris. When he was there Papin was greatly interested in the relief of painful hydronephrosis by an operation consisting of severing the entire nerve supply of the kidney, and fixing that organ to the twelfth rib. His results had been most successful. In London, Mr. E. C. Ryall, and his assistant, Mr. Attwater, had established All Saints Hospital for genitourinary diseases. They said they had made great advances in the treatment of inoperable tuberculosis of the urinary tract by giving gradually increasing doses of old tuberculin until the patient might be receiving as much as two c. c. every three days. Dr. Lowsley said that he found the clinics and institutions as a whole in bad condition from the economic state of the countries; France seemed the most prosperous. The condition of the general practitioner, also, was everywhere bad; people cannot afford to employ them. University students in Germany and Austria attended lectures or classes until about 2 p. m., then went about earning their daily bread. Among things of particular interest reported by Dr. Lowsley were:

In St. Joseph's Clinic in Berlin a substance was used called Ri Venol which gave good results in relieving extreme cases of bladder irritation due to tuberculosis; in both Paris and Berlin, enthusiasm was displayed for the heat coagulation destruction of tumors of the bladder; it was pleasing to note that in every country visited the cystourethroscope of Dr. Joseph F. McCarthy was in general use; no one but Rosenstein seemed enthusiastic about the perinephritic insufflation of gas in kidney conditions; and no one but Steinach about the rejuvenation experiments; there was considerable secrecy about the discovery of a new cure for sleeping sickness developed at the hygienic institute for tropical diseases at Hamburg by Dr. Bayer, and called Bayer 205; the originator asserted that it was a trypanocide, and might be used in any disease caused by spiral organisms. On the whole, it seemed that Americans were doing much more for the advancement of medical science than their European confrères could do for some years to come. The Rockefeller Foundation was doing an excellent thing for Europe by erecting a hygienic barrier between Western Europe and Russia, whence most of the epidemics originate at present. Every courtesy was extended to foreigners, especially in Austria and Germany, where was evident a greater friendly professional interest in medical visitors than in France or England. Dr. Lowsley closed his paper by emphasizing the necessity of America's doing something to relieve the condition of the general practitioner in Europe, who is practically destitute, particularly so in Austria.

Discussion.—Speaking of Dr. Valentine's case, Dr. Beer said that he had seen the patient when cystoscoped, and questioned whether the lesion had had anything to do with the symptoms. He stated that in his experience a leukoplakia of the urinary tract did not occur in the course of syphilis, but was apparently of congenital origin. He suggested that, if Dr. Valentine should decide to operate, he destroy the area of the leukoplakia, since these spots were likely to lead to epitheliomatous growths.

Dr. A. L. **Dean** declared that he was much interested in Dr. Townsend's case, which he had treated at the Memorial Hospital. He would like to hear the result of the pathologist's examination of the inguinal nodes in this case. Dr. **Rathbun** said he had had four cases of extirpation of the penis, but in none of these was the scrotum or its contents extirpated. One patient had died later of metastases of the lung; he had had no postoperative treatment. The others were alive several years after the extirpation; they had been subjected to x ray therapy after the extirpation. He had just completed a postoperative technic; instead of plastic surgery, he simply put in a few stitches, and packed the wound with iodoform gauze. Dr. Townsend replied by saying that he still felt that the more mutilation at the operation the greater the chances of success, particularly in the case recorded. Dr. **McCarthy** said that the point brought out in the history by Dr. **Killian**, that the improvement was marked after the passage of the calculus, was subject to considerable modification, inasmuch as it was not until the 8th that the calculus was passed, whereas it was on the 4th that the duodenal lavage was inaugurated, and on the 10th the blood chemistry findings showed 56 urea nitrogen and 9.2 creatinin. It was, therefore, a reasonable supposition that the great bulk of the improvement from the 4th to the 10th must have been due in large measure to the duodenal lavage rather than to the passage of the calculus, which occurred only two days prior to the 10th.

Dr. **Beer** said the case interested him from many points of view. One particular feature he hoped Dr. McCarthy could elucidate, namely, Was there any chance in this case, in view of the uric acid calculi, that the patient had a bilateral ureteral obstruction with uric acid stones? If there was no proof that he had not, the explanation on a reflex basis would not be accepted. Dr. Beer said he was greatly interested in the subject of reflex anuria, and had collected several cases. Personally he believed that reflex anuria could occur, but in view of the fact that this patient had stones that cast no shadow, a justifiable doubt existed as to whether the second ureter was not also blocked when the anuria set in. It was interesting to hear that Dr. McCarthy had been able to influence the kidney so favorably with the duodenal tube flushing; it was perhaps a new method of getting stones down the ureter.

Letters to the Editor.

PLEA FOR INSTRUMENTS AND MEDICINES FOR PERSIAN PHYSICIANS

Brooklyn, N. Y., *July 31, 1923.*

To the Editor:

I am wondering if there are some of the members of the medical profession who would be willing to help out a fellow physician who is doing a fine work in far away Persia. Dr. Solomon Werda was educated in Long Island College about twenty-five years ago and returned to Persia, where he has been at work ever since, making bricks without straw, for the field is large and medicines and instruments few. Several times he has been robbed of most that he had, and had to beg his friends for help.

It has occurred to me that there might be some of the simpler and most commonly used instruments lying unused and practically discarded in some doctor's office that would be most useful to Dr. Werda. It would be a pleasure to us to know of any such, and to send them to him. I should be glad to forward any contributions to Dr. Werda. His need of medicines is quite as great, and what he can get are so expensive as to be prohibitive, and yet they are necessary.

Dr. Werda was within the war zone and some of his losses were due to that fact, perhaps because he was personally able to save the lives of five hundred soldier refugees when they were about to be surprised and captured by the Turks.

389 Clermont Avenue.

MODERN MEDICAL KNOWLEDGE

New York, *August 19, 1923.*

To the Editor:

In looking over my medical journals nowadays I rarely find an article which teaches what avails in ordinary practice. Lately, it is true, we have to do with insulin as a remedy in diabetes. It was thought at first to be sure, without flaw. At present we know there are drawbacks in its use and unless the wise practitioner handles it, trouble or death may result. Of course, we know that the remedy is due to laboratory research and we are glad that the discoverer has received honors from the government (Canada), and abundant praise from his colleagues. And yet, is it not true already, that it may soon be displaced in practice by a modified fat more lately found and vaunted?

The fact is, despite all advances in medicine and surgery, we go around, as it were, in a circle. Things come and things go, but it still remains true that the old time remedies with the changes that many trials have brought in their use, still remain in the great majority of instances the agents we regard as most reliable and freest from possible great harm to the patient.

Everyone, almost, who reads the foregoing, will exclaim that the writer is a back number, and should not be counted. He merely rings praises over the past and does not, or cannot, profit by the present. To this criticism I fail to adhere, because if I did I should ignore and throw aside much, not to say all, of what I learned from former preceptors and lifelong experience.

What I should like to see today would be a medical journal filled with readable articles to guide and direct those men in general practice who are daily caring for ill patients at the bedside and not simply performing stunts in the laboratory and who, when called upon to minister professionally to the ill and suffering, are so scientific that they know, or do very little to help, or relieve. Cure is something they often retard, or prevent, by their doing, alas, whether it be medical or surgical.

Beverley Robinson, M. D.

Abstracts from Current Literature

GENITOURINARY DISORDERS.

Practical Experiences with the Intravenous Treatment with Glucose.—H. Planner (*Wiener klinische Wochenschrift*, August 17, 1922) relates his experiences at Finger's clinic in over one hundred cases, mostly of fresh secondary syphilis, with a ten to fifty per cent. glucose neosalvarsan solution. He found that this form of treatment had no great advantage over the ordinary salvarsan or combined salvarsan mercury treatment. He emphasizes the prompt symptomatic effect, but the permanent results did not come up to expectations—the general course of events presented the usual picture and early neurorecidives were also not avoided with this form of treatment.

Syphilis as a Cause of Antenatal Death.—J. N. Cruikshank (*British Medical Journal*, September 30, 1922), from a study of the Wassermann reaction in thirty-five hundred specimens of blood and the clinical records of one thousand pregnant women concludes as follows: 1. That between nine and ten per cent. of women of the hospital class in Glasgow show evidence of syphilitic infection; 2, that the results of the Wassermann reaction in the blood of the newborn are of little value in proving the presence of congenital syphilis; 3, that the incidence rate of congenital syphilis has been greatly exaggerated by most of the recent writers; 4, that maternal syphilis cannot be shown to be a factor of predominating importance in the etiology of the interruption of pregnancy in the earlier months; and 5, that syphilis is one of the most important causes of stillbirth and of the interruption of pregnancy in its later months, leading to premature birth, and, more particularly, to premature birth with death of the fetus.

Statistics on Prematurity and Congenital Syphilis.—With the aid of statistics, E. Kehrer (*Zentralblatt für Gynäkologie*, February 10, 1923) shows that syphilis does not play a very important part as the direct cause of premature births and that it certainly does not possess the great significance which has been ascribed to it, but that the prognosis for all children borne by a syphilitic mother is a grave one, and that, both during their intrauterine development as well as their susceptibility to external influences after their birth. According to the author's statistics, syphilis does not, as is generally assumed, cause sixty to ninety per cent. of premature births, but only seven per cent. On the other hand, it does frequently cause intrauterine death of the fetus and death of the premature fetus after its birth.

A Study of the Inorganic Constituents of the Blood Serum in Nephritis.—W. Denis and S. Hobson (*Journal of Biological Chemistry*, February, 1923) studied the inorganic constituents of the blood serum in twenty-two cases of nephritis and cardiorenal disease, with the following results: The sodium and chlorine showed a marked increase over the normal in only four cases; the inorganic phosphate fraction was increased in ten cases; the inorganic sulphates showed increased values in eleven instances; magnesium and potassium were more or less constant, and calcium decreased in five cases. In discussing these results the authors state that the contrast afforded by the behavior of the sodium and chlorine, on the one hand, as against phosphate and sulphate, on the other, justifies the suggestion that we have here a demonstration of the specific selective activity of the kidney towards the various normal inorganic constituents of serum, somewhat similar to the selective action which has been shown to exist for the various nonprotein nitrogen constituents of the blood. Sodium and chlorine are excreted with great ease and even in the case of the badly damaged kidney, retention of these elements seldom occurs; in this respect they may be said to resemble creatinine. The sulphate ion is apparently excreted with difficulty, so that in kidney insufficiency the concentration of this fraction may increase enormously; in this respect, the sulphate ion may be compared to the uric acid fraction, although the percentage increases observed are far above any concentrations of uric acid so far reported.

Chloride Retention in Experimental Hydronephrosis.—Norman M. Keith and D. Schuyler Pulford, Jr., (*Journal of Experimental Medicine*, February, 1923) produced hydronephrosis in dogs by partial obstruction of both ureters near the ureteropelvic juncture. Chloride retention, as well as the retention of water, urea, and phenolsulphonephthalein, occurred in acute hydronephrosis. If water and chlorides are equally retained in the body, the plasma concentration of chlorides will not rise appreciably. When chlorides are retained, but not water, there is an increased concentration of chlorides in the plasma. When the ureteral obstruction is removed all the renal functions, water, urea, and chloride excretion, may be rapidly restored in equal degree, or there may be a free excretion of water and urea, and a temporary chloride retention. The one example of chronic hydronephrosis studied showed that under the experimental conditions the chloride metabolism differed little from the normal. A polyuria seemed to be the compensatory mechanism which prevented any marked retention of chlorides, urea, or water.

A Study of the Relation of Treponema Pallidum to Lymphoid Tissues in Experimental Animals.—Louise Pearce and Wade H. Brown (*Journal of Experimental Medicine*, January, 1922) demonstrated that only forty-eight hours after inoculation of the scrotum of the rabbit, the inguinal nodes contain active Treponema pallidum; the syphilitic infection is sufficiently established after that time so that the primary lesion is no longer essential for its maintenance. Further experiments indicate that for long periods of time Treponema pallidum may be present in the lymph nodes of rabbits which have recovered from clinical manifestations of the disease, even though no further manifestations of the infection occur, and further that the reservoir of the organisms during latent periods of syphilitic infection is lymphoid tissue. This intimate relation of Treponema pallidum to lymphoid tissue is an essential concept of syphilis of the rabbit, and from this point of view the infection is primarily one of lymphoid tissue.

Focal Embolic Glomerulonephritis.—Margaret Warwick (*Journal of Laboratory and Clinical Medicine*, June, 1922) analyzes ten cases of focal embolic glomerulonephritis which occurred in the autopsy records of the Department of Pathology of the University of Minnesota during the past five years. The cases all showed enlarged spleens, the persistence of microscopic red blood cells in the urine, a varying phenolphthalein value, sometimes very low, and again approximately normal. Most of the cases were associated with the presence of the Streptococcus viridans; in one case, however, which showed the classical ulceration and vegetations of the mitral valves and presented typical lesions, Streptococcus hemolyticus was recovered from the blood, showing that streptococci other than the viridans may be responsible for focal embolic glomerulonephritis. In all ten cases the heart was enlarged; the mitral valve was involved alone five times; the mitral and aortic together four times, while the aortic alone was involved but once. The lesion consisted of vegetations sometimes accompanied by ulcerations of the valve leaflets. In the series there were also five cases showing multiple infarcts of the spleen, kidneys and often brain, confirming the theory that these lesions are the result of tiny emboli lodging in the loops of the glomeruli.

The Course of Syphilis and the Jarisch-Herxheimer Reaction; the Excretion of Mercury and Salvarsan in the Reaction.—Moriz Oppenheim (*Wiener klinische Wochenschrift*, January 4, 1923) observed 128 Jarisch-Herxheimer reactions among 180 cases of syphilitic exanthema. He comes to the conclusion that the cases showing intense reactions were those with a subsequently unfavorable course, developing recurrences in the liver, eyes, bloodvessels and nerves and fluctuations in the Wassermann reaction. During the reaction there is a greater retention of mercury or salvarsan in the body. The cause of this unfavorable course has not as yet been explained. Except in the cases that require abortive treatment, therefore, the author advises the avoidance of an excessive reaction and that the treatment should be commenced with a course of inunctions or other small doses of mercury before resorting to more energetic treatment.

Wildbolz's Own Urine Reaction.—After carefully describing the technic of this test and after reporting two hundred of his own cases and 2,300 cases in the literature, R. Kipfer (*Schweizerische medizinische Wochenschrift*, December 30, 1922) found that of 1,433 patients recognized clinically as tuberculous, 90.1 per cent. showed a positive Wildbolz reaction. If the cases that failed to show a skin reaction are excluded, there were 92.7 per cent. of positive results. Of 845 cases, in which the clinical methods of examination failed to show tuberculosis, 68.8 per cent. reacted positively; excluding infants, whose skin is unsuitable for this test and also practically unnecessary, there were 28.8 per cent. positive results. Most of the deviating results are explainable by sources of error which may be corrected. Some positive reactions in isolated cases of staphylococcus infection, typhoid fever, nephritis, malignant tumor, syphilis and progressive paralysis are still unexplained. The author concludes that the Wildbolz own urine reaction is a method of immunological diagnosis of tuberculosis of practically great importance, inasmuch as it is an advance on the previous clinical diagnosis of tuberculosis in its diagnostic breadth and is, therefore, a valuable complement of the latter.

Clinical Experiences with Wildbolz Own Urine Reaction.—Karl Schmid (*Schweizerische medizinische Wochenschrift*, March 8 and 15, 1923) found that in patients afflicted with tuberculosis the Wildbolz own urine reaction is produced by substances that are peculiar to this disease, that the positive result is not produced only by these substances, but also occurs in other diseases, as in carcinoma, and that in advanced, chronic bronchitides which do not appear to be tuberculous, positive reactions occur every now and then. According to some of the author's observations, it appears in place to investigate whether a positive nonspecific Wildbolz reaction may not occur in advanced age, particularly as a symptom of senility; probably as a result of a marked decomposition of albumin. In some cases of streptococcus and pneumococcus sepsis, analogous to the cases of nephritis and staphylococcus diseases of the urinary tract, a positive reaction also occurs. The reliability of the Wildbolz reaction seems to be impaired by the fact that the substances excreted in the urine and which are responsible for the reaction can be used only in very small amounts for purposes of inoculation and the test, therefore, must be frequently repeated.

Sulfarsenol in the Treatment of Syphilis and of Some of the Complications of Gonorrhea.—F. Carminow Doble (*Lancet*, January 13, 1923) states that sulfarsenol may be given intramuscularly or subcutaneously without causing great pain. Besides the increased therapeutic effect, the patient need not be subjected to starvation before and after the injection. The results are uniformly good. The spirochetes disappear from the lesions in twenty-four and forty-eight hours after an injection of this drug. The clinical results and the effect on the Wassermann reaction of the blood equals those of any other drug. The action on the spinal fluid is not so markea as that of silver salvarsan. In those cases, in which the other arsenicals could not be given, clinical improvement followed the injection of small doses of sulfarsenol, which were gradually increased. A Herxheimer reaction occurs in less than one per cent. of cases. There is no better drug for infants than sulfarsenol, provided the dose is controlled by the body weight of the child. Pregnant women can be treated up to childbirth and then mother and child can be treated separately. If pain occurs, it is probably due to the water not being absolutely fresh and sterile. The patient is not inconvenienced nor does he have to lose time from work. For the treatment of the complications of gonorrhea the intravenous route is the best. The author tried this drug in cases of arthritis, rheumatism, hyperkeratosis and epididymitis. The results were remarkably good, but the effect in epididymitis was extraordinary. The dose was 0.12 gm. followed in forty-eight hours by an injection of 0.18 gm.; if the pain returned, an injection of 0.18 gm. was then given, followed by another injection forty-eight hours later of 0.3 gm., when the temperature dropped and the pain disappeared permanently.

Therapeutic Action of Bismuth in Syphilis.—C. Levaditi (*Lancet*, March 31, 1923) states that sodium and potassium tartrobismuthate and metallic bismuth achieve rapid cicatrization of syphilitic lesions at all stages of the disease. Although bismuth has only been recently employed, he has every reason to believe that when used early and in sufficient quantity, it will cure syphilis. The absence of recurrences of the disease and the effect on the Wassermann reaction serve only to confirm this opinion. Equal, from a therapeutic point of view, to arsenical preparations, better than mercurical preparations, bismuth (trépol and neotrépol) is a valuable antisyphilitic remedy, particularly in those manifestations of the disease which resist the action of arsenic and mercury. In oily suspension this preparation is nontoxic. Insoluble preparations should be used for intramuscular injections, preferably in the superior gluteal area. The intravenous route is dangerous. The dose should be two c. c. (0.2 gram of the active preparation), repeated every three or four days, until a total amount of 2.8 or three grams has been reached. The series of injections should be repeated after an interval of a month, until the Wassermann reaction becomes negative.

Contraindications to the Intensive Treatment of Syphilis.—U. J. Wile (*Medical Clinics of North America*, March, 1923) deprecates the present tendency to treat disease by routine methods rather than the patient himself. Where visceral syphilis exists treatment may be required not only from the side of the syphilis, but from the viewpoint of the affected viscus as a dysfunctioning organ. Syphilis cannot be treated in any routine fashion, as this implies injudicious treatment, treatment that should not have been given at all, or overtreatment; each individual patient requires individual treatment according to the exigencies of the case.

The course of the treatment should be governed, in the first place, by the age of the syphilitic. A second factor to be considered is the duration of the syphilis; this also involves a difference in prognosis. A third factor is the presence of coincident disease other than syphilis. The next factor requiring consideration is the type of the syphilitic lesion present. Another important factor is the social status of the individual, taking into consideration the syphilitic as a carrier and disseminator of the disease. There are unquestionably many cases of old syphilis which should not be subjected to treatment, especially when the Wassermann reaction is interpreted as an absolute guide to therapeusis and an invariable indication, so to speak, for treatment. These are the patients who have received adequate treatment, who have lived their lives, and are useful members of the community, without danger to themselves or to the community, who have, so to speak, outlived their syphilis and yet whose blood tests are permanently positive—the socalled Wassermann fast cases. There is another group of syphilitics, in which treatment is utterly hopeless and may even result in real damage: it is hopeless in demented paretics (later stages) and it is dangerous in the very severe cases of myelitis and of tabes, in which so great a destruction of the cord has already occurred that there is complete paralysis and incontinence of both urine and feces; the same applies to the more rare cases of syphilitic transverse myelitis and other severe syphilitic injuries in the cord, excepting gumma of the brain or cord.

The first requisite in the treatment of syphilis is a complete survey and evaluation of the patient, not only from the viewpoint of his disease, but from the particular position he occupies in society, from the viewpoint of what can be accomplished by treatment, from the careful study of the predominating features of the disease, with due regard for the peculiarities of the particular system involved; also, what is most important, the acceptance of the fact that the biological test in itself is not of necessity an indication for therapeutic intervention.

Treatment of Epithelial Tumors of the Urinary Bladder.—Frank Kidd (*Lancet*, March 17, 24, and 31, 1923) concludes as follows: 1. Biopsies in cases of papilloma of the bladder are unnecessary and even dangerous, as about ninety per cent. of patients are cured by diathermy treatment through the cystoscope. 2. Even in some cases of doubtful malignancy a certain number of cures may be obtained in this way. 3. In cases of malignant papilloma, early papilliferous carcinoma, and even of early ulcerating carcinoma of the bladder, subtotal or partial cystectomy is indicated. Cases of partial cystectomy should be followed up at regular intervals by means of cystoscopy. 4. Total cystectomy has been almost replaced by partial cystectomy, diathermy, and radium. It should be reserved for cases of multiple malignant papillomata refractory to other treatment and for a few favorable cases of early carcinoma involving both ureteral openings. 5. Ureterostomy presents almost as great a risk to life as total cystectomy. It may be used as a preliminary to total cystectomy in a few favorable cases. 6. In the author's opinion, radium has not yet justified its claim to supersede surgery, but it has established a claim to the closest consideration. It has already replaced total cystectomy, combined perhaps with open fulguration and deep röntgen ray therapy. Socalled inoperable cases should not be simply drained or let alone; these bladders should be opened and treated either by open diathermy or fulguration combined with the implantation of radium emanation glass tubes, perhaps followed up by deep röntgen ray therapy and cystoscopic application of radium and diathermy.

The Cerebrospinal Fluid in Congenital Syphilis.—Max Frank (*Monatsschrift für Kinderheilkunde*, A. Czerny Festschrift, March 25, 1923) states that an increased amount of albumin, lymphocytosis, or a positive Wassermann reaction in the cerebrospinal fluid were found only in such cases as showed florid symptoms and in patients who were insufficiently treated or not treated at all up to the day of the lumbar puncture. With the aid of the gold sol reaction he was enabled to recognize a larger percentage of the cerebrospinal fluids of congenital syphilitic infants than pathologically, using only the reactions in ordinary use. By doing only a gold sol reaction on the cerebrospinal fluid of syphilitic infants in certain cases, which do not differ from other syphilitic children in regard to the results of the other reactions, the severe changes in the cerebrospinal fluid can be demonstrated.

The Present Conception of the Question of Metasyphilis.—E. Redlich (*Wiener klinische Wochenschrift,* March 8 and 15, 1923) says that there is no longer any doubt as to the syphilitic nature of locomotor ataxia and of general paralysis. However, the pathological, anatomical, and clinical phenomena are not as yet fully explained by the demonstration of the Spirocheta pallida, inasmuch as the investigation of this complicated question is still in its beginning, and therefore most of the hypotheses regarding the nature of locomotor ataxia and of general paralysis are still questionable. The assumptions of Gennerich are particularly objectionable.

Wassermann and Flocculation Tests: Compared in One Thousand Cases.—A. L. Urquhart (*Lancet,* January 20, 1923) concludes: 1. That the flocculation test gives as reliable results as the Wassermann reaction. 2. That the flocculation test is preferable to the Wassermann reaction on account of its greater simplicity. 3. That sheep's heart extracts make satisfactory antigens, and that similarity of antigenic property may be obtained by adjustment of the amount of cholesterol added to the heart extract. 4. That contamination of hemolysis in the sera may give rise to false positive readings and such sera should not be used in the test. 5. That the presence of bile pigment, or an anticomplementary state of the serum, does not interfere with the flocculation test.

Selective Action of the Kidney as Regards the Excretion of Inorganic Salts.—W. Denis (*Journal of Biological Chemistry,* February, 1923) injected solutions of various inorganic salts directly into the intestine of anesthetized dogs, and then analyzed samples of serum, and in some cases whole blood, taken at intervals over a period of several hours. Salt solutions were also injected intravenously, and the rapidity of excretion determined by blood analyses. The results indicate a selective retention on the part of the kidney for the sulphate ion, which in one case was found to accumulate in the serum to a value of 3,200 per cent. of its initial concentration. The salts used in this work were magnesium sulphate, sodium sulphate, magnesium chloride, sodium chloride, and sodium phosphate.

Outlook of Nephritis in Children.—Hugh T. Ashby (*British Medical Journal,* March 10, 1923) finds that about ten per cent. of patients afflicted with scarlet fever suffer from a subsequent nephritis. The outlook in these cases is generally good and the nephritis rarely becomes chronic. The amount of albumin in the urine seems to bear no relationship to the prognosis. The most serious cases are those which have received no treatment for several days and those showing suppression of urine, in which uremia may occur. The prophylactic treatment includes the avoidance of exposure to cold, particularly during the two or three weeks following the onset of the scarlet fever. The prognosis is usually bad in cases of acute nephritis, as they run a course lasting from three months to two years and complete restoration to health does not occur often. The patient may recover partially, but the recurrent attacks aggravate the damage to the kidneys until anasarca develops and death follows. Finally the urine is very much reduced in amount and dyspnea becomes very prominent. Uremic convulsions may also occur.

Functional and Anatomical Study of the Excretion of Hemoglobin by the Kidney.—Yoshu Fukuda and Jean Oliver (*Journal of Experimental Medicine,* January, 1923) gave male rabbits a moderate intravenous injection of normal saline or one hundred c.c. of water by stomach tube. Thirty minutes later the animals were catheterized and given an intravenous injection of hemoglobin solution in normal saline. At fifteen minute intervals the catheterization was repeated, the bladder each time being washed out with a known amount of water. In these specimens the amount of hemoglobin was determined. Ten such experiments were done. From the results obtained the authors conclude that the anatomical and functional findings in hemoglobin excretion are best explained by the assumption of a filtration of this substance through the glomerulus and an additional excretion of it by the tubule cells. Absorption of water aids in the concentrating process, and is most marked in the collecting tubules.

Syphilis of the Lung.—W. T. Munro (*Lancet,* December 30, 1922) states that acquired syphilis of the lung may occur in three conditions, namely, gummata, fibroid induration, and areas of consolidation and catarrh, of which fibroid induration is the most common. In these cases the initial lesion would appear to be at the right base. In the author's cases no patient was under thirty-five years of age. The shortest time between infection by the spirochete and symptoms referable to the chest was three and a half years. Antisyphilitic treatment in the early stages is to be recommended, but when the bronchiectasis is well established treatment is not likely to lead to improvement. Two cases of focal disease were found; both improved on treatment. This condition occurs in younger patients. Congenital syphilis of the lung may be of common occurrence and responds to treatment.

A Study of the Austin-Stillman-Van Slyke Index of the Urea Excretion.—Charles H. Hitchcock and Ruth Loveland (*Bulletin of the Johns Hopkins Hospital,* August, 1922) determined the Austin-Stillman-Van Slyke urea excretory coefficient in twenty-seven cases. They found a definite lowering of the value of the coefficient in borderline conditions, as well as in cases presenting marked evidence of renal damage, and during the relapses of pernicious anemia. They conclude that the use of this index may be of value in demonstrating renal insufficiency, and it is particularly worthy of study in borderline cases.

Byeffects of Arsphenamine.—Ernst Slawik (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) states that the byeffects of arsphenamine are usually of a harmless nature. However, it is a source of danger to the infant in febrile processes, which must be considered as a strict contraindication. It must also be feared in decompensation; the arsphenamine must not be discarded entirely from the beginning, but it must be administered very cautiously under constant control of the gastrointestinal symptoms; with the signs of not being well tolerated, which is determined chiefly by the weight curve, further treatment with arsphenamine should be discontinued possibly for several weeks.

CARDIOVASCULAR DISEASES.

Diagnosis of Endocarditis.—George R. Herrmann (*Medical Clinics of North America*, March, 1923) asserts that the diagnosis of subacute bacterial endocarditis in cases with persistently negative blood cultures must be made only after thorough study of the case which presents some of the characteristic signs. One positive blood culture is not to be considered sufficient basis for the diagnosis which has such a grave prognosis, unless symptoms and signs fit into the picture. A systolic murmur over the heart in cases with fever should not be considered too seriously; diastolic murmurs always demand more serious consideration and certainly lend considerable weight to the diagnosis of a subacute bacterial endocarditis. It is important to secure exact details in the physical examination. The murmur of the congenital heart lesion may easily be misinterpreted. The diagnosis of an exacerbation of rheumatic endocarditis may be made because of the absence of evidence of embolism and infarction before the onset of cardiac failure. Positive blood cultures may be obtained with comparatively little difficulty and therefore repeatedly negative blood cultures acquire considerable significance. The facts necessary for a diagnosis of subacute bacterial endocarditis are principally these: the signs of a definite organic heart lesion, of a prolonged sepsis with fever and anemia, and of embolism; positive blood cultures added to these findings make the diagnosis practically certain.

Acute Intermittent Cardiac Decompensation.—Elsworth S. Smith (*Medical Clinics of North America*, July, 1922) finds that the most characteristic feature of this group of cases is the intermittency of the attacks of decompensation. The attacks occur suddenly, mostly in the early morning hours, with a severe dyspnea progressing to cyanosis and ending in orthopneà with cold, clammy sweats and a rapid and at times imperceptible pulse; also cough, with bloody, frothy expectoration, often copious, numerous bubbling râles over the bases of the lungs, especially posteriorly, and resulting edema and circulatory collapse. Prompt medical aid may prevent a fatality. The treatment of these cases includes that of the attack and that of the intervals. During the attack, if arterial hypertension is present, one fiftieth grain nitroglycerin is given hypodermically and repeated every fifteen to thirty minutes as necessary, and one twenty-fifth grain of reliable digitalin should be given every half to one hour, and one twentieth to one thirtieth grain strychnine sulphate as required. To calm the patient's mind, one fourth grain morphine and one fiftieth to one one hundredth grain of atropine sulphate are given and repeated as necessary. An ampoule of camphor is given hypodermically every fifteen minutes until the patient rallies. Oxygen relieves the cyanosis. If there is no arterial hypertension the treatment is practically the same, with the exception of the omission of the vasodilators; if the symptoms of angina pectoris predominate, morphine may be used freely.

During the intervals between attacks, arterial hypertension must be controlled by the elimination of coffee, tea and nicotine; alcohol may be allowed in moderation to those accustomed to its use and to the feeble, provided there is no serious grade of nephritis. If the nonprotein nitrogen in the blood is excessive, a low protein diet is indicated, especially with an impaired renal function. Focal infections must be sought and eliminated. All the emunctories of the body should be kept in an active state. Vasodilator drugs should be kept in reserve for the attacks or continued over periods when there may be a tendency to repetition of the attacks from high blood pressure, or when the hypertension proves intractable to treatment. For administration over longer periods of treatment, sodium nitrite, in doses of one to three grains daily, or erythrol tetranitrate in 0.5 grain doses, both given three times daily, are preferable; sodium or potassium iodide in ten to twenty drop doses, well diluted, may also be used. Bromides help with a severe nervous element. In the involutionary type of arteriosclerosis without hypertension, the excessive use of salt should be controlled. Syphilis should be looked for and in its presence iodides are indicated. Undue physical effort and dietary indiscretions and venery should be avoided.

Use of Quinidine in Auricular Fibrillation.—Francis R. Fraser (*British Medical Journal*, March 24, 1923) comes to the following conclusions: 1. Quinidine treatment will result in a stable normal rhythm if the cause of the auricular fibrillation can be successfully treated or has ceased to be active. 2. Cases in which there are extensive structural changes in the heart are not suitable for quinidine treatment, especially if the response to digitalis is not good, as dangerous symptoms may result. 3. In some cases at least the comfort and efficiency of the patient are greater when a normal rhythm results from quinidine treatment than when digitalis treatment alone is used. 4. In the cases in which the results are satisfactory larger doses than ten grains of quinidine sulphate at intervals of six hours were not necessary, nor smaller initial doses than five grains three times a day. 5. If necessary to maintain normal rhythm, quinidine may be continued to be administered indefinitely in doses of at least five grains three times a day, and it is probably advisable in all cases to continue it for some weeks after normal rhythm has resulted, though in gradually decreasing doses.

An Experimental Investigation of the Pharmacological Action of Quinidine.—D. E. Jackson, Alfred Friedlander, and J. V. Lawrence (*Journal of Laboratory and Clinical Medicine*, March, 1922) studied the action of quinidine on the irregularities of the hearts of dogs, caused by aconite, digitoxin, and barium. These drugs were chosen because they set up cardiac arrhythmias more nearly like the cardiac irregularities occurring clinically than any others. From their experiments they state that quinidine undoubtedly acts on both auricles and ventricles; it tends to counteract the development of fibrillation of the ventricle after such drugs as aconitine or digitoxin. One of the earliest actions on the normal heart is a slight dilatation of the ventricle as shown by the cardiometer. The authors surmise that in due time it will be found that quinidine acts on the musculature of the peripheral vessels, and perhaps even on the skeletal muscles, in a manner similar to that in which it acts on the heart muscle. The decrease in the power of adrenaline to raise the general blood pressure after quinidine may indicate an action on the sympathetic innervation.

RADIOTHERAPY.

Technic of Diathermy and Indication for Its Use.—R. Grünbaum (*Wiener klinische Wochenschrift,* January 11, 1923) has improved his technic of diathermy therapy of chilblains to such an extent, that he uses this treatment even in the severest cases of frostbites. For example, have the patient place the tips of his toes in running water and apply the other electrode to both thighs, with the result that the current flows from the tips of the toes through the entire leg and thus affects a large vascular area. In addition to frostbites a suitable field of diathermy treatment are the diseases of the accessory nasal sinuses, cicatricial bands and abdominal adhesions; also chronic parametritis and perimetritis.

Use of Radium in the Treatment of Disease.—Dawson Turner (*British Medical Journal,* March 17, 1923) found radium useful in malignant disease, exophthalmic goitre, splenomedullary leucemia, Hodgkin's disease, keloids and nevi. The malignant affections included rodent ulcers, epitheliomata, lymphosarcomata, spindlecelled sarcomata, malignant disease of the cervix, sarcomata of the nasal passages. Second class subjects, those which may be ameliorated but not actually cured, are carcinomata, lymphadenomata and splenomedullary leucemia.

Small, rodent ulcers not affecting the mucous membrane or bone are easily cured by a dose of five hundred to eight hundred milligram hours through a filter of silver 1.5 millimetres thick; smaller doses may allow a recurrence. Rodent ulcers near the alæ nasi and those on the ear or just below it are more refractory. Unless completely cured by the first treatment they tend to become radioresistant and further exposures may be harmful. Small epitheliomata of the lip are quite amenable to surface applications, but when the floor of the mouth, tongue, or fauces are involved, it is difficult to benefit materially the condition with radium. Lymphosarcomata are the most susceptible to radiations. In gynecology the best results are obtained in malignant disease of the cervix with six thousand to ten thousand milligram hours at the first treatment.

In the treatment of exophthalmic goitre and of nevi in children by radiation, radium has the following advantages over x rays: 1. Absolutely constant emission of rays, and therefore exact dosage is possible. 2. Greater penetration of rays, so that the deeper parts are reached. 3. Saving of time (radiation night and day). 4. The elimination of noisy, exciting apparatus, which can be applied at the bedside without alarming the patient.

Röntgen Injuries and Deep Röntgenotherapy.—W. Latzko (*Wiener klinische Wochenschrift,* March 15, 1923) aims to avoid the severe injury to the circulating blood. Starting from the assumption that with an irradiation lasting several hours the bloodvessels of the pelvis and of the abdominal viscera circulate the entire mass of blood of the body many times and that consequently the blood is subjected to the influence of the röntgen rays in a very intensive degree, it seems plausible to exclude a large portion of the blood from the circulation during the irradiation so as to eliminate the effect of the röntgen rays upon a large portion of the blood. This the author endeavors to accomplish by constriction of the lower extremities during the treatment with elastic bandages, so that a considerable congestion results. The blood retained in the lower extremities in this manner is completely or almost completely protected from the effects of the rays. After the exclusion of the circulating blood, those organs and tissues which must be made responsible for the severe injury of the general condition should be protected from the rays. The work of the future lies in finding new ways of accomplishing this.

Treatment of Malignant Disease by X Rays.—J. H. Douglas Webster (*Lancet,* February 24, 1923) subscribes to the views of Schmieden and Holfelder, which represent what may be called cautious progressive present day opinion: 1. With few exceptions every operable carcinoma should be operated on, with prophylactic postoperative irradiation in addition. 2. In addition to postoperative irradiation a single intensive irradiation before operation is coming to be considered important. 3. Practically all inoperable carcinomata and all inoperable recurrences should be irradiation. This gives in many cases clinical cure, in others it results in operability, often less bleeding, irritation and pain, as well as limitation of further metastases. 4. Facial carcinomata, even when operable, can well be treated exclusively by irradiation for cosmetic reasons. 5. Sarcomata, as a rule, should only be irradiated, certainly in all cases in which operation would cause considerable bodily mutilation. (Any increase in size of the tumor after an efficient irradiation should not be considered proof of failure to respond, as it is usually only temporary.) 6. In the treatment of malignant tumors, along the whole line, x ray work has become superior to radium treatment, except in the form of the American radium technic of burying numerous small tubes and of massive surface irradiation from a distance. The time has not yet come when statistics can show the comparative values of operation or irradiation in the treatment of malignant disease.

Present Day Treatment of Asthma*

By AARON BROWN, M.D.,
New York.

The modern treatment of asthma is based upon the principles of desensitization in animals, introduced by Besredka. He found that a sensitive animal could always be rendered specifically and completely insensitive by a suitable and gradual neutralization of antibodies, which are responsible for the hypersensitiveness (desensitization). In 1911, Freeman and Noon (1, 2) in England, and Dr. Robert A. Cooke (3), independently in this country, made successful use of this concept in the treatment of hay fever and asthma.

It is immaterial to the patient, whether the process involved is that of actual desensitization or not. He is concerned only with the results obtained. As a matter of fact, the process is not that of desensitization, for we must distinguish between anaphylaxis, or animal hypersensitiveness, and allergy, or inherited hypersensitiveness in human beings. Dr. Arthur F. Coca was the first to differentiate the two (4).

In brief, some of the differences between the two are:

1. In anaphylaxis, the exciting agent is antigenic (capable of producing specific antibodies). In allergy, the exciting agent is often not antigenic, it may be a drug; no specific antibodies are produced.
2. Anaphylaxis requires two injections, one to sensitize and the second to shock. In allergy, first contact often is sufficient.
3. Anaphylaxis is artificially induced; allergy s inherited.
4. In anaphylaxis, complete desensitization is always successful. Not so in allergy; positive skin reactions always persist, although they may be modified. A small dose of a specific protein, for example, in hay fever, has been known to stop all symptoms for several years. This is unknown in anaphylaxis. In fact, after a time the animal becomes more sensitive.

What the actual process in human beings is, we do not know. For practical purposes, however, the treatment of asthma divides itself into, first, the treatment of the paroxysm and secondly, the interval treatment. Cases of dyspnea due to renal or cardiac disease, the socalled renal and cardiac asthma, are not included in this paper.

The actual attack is controlled most efficiently by adrenalin. To obtain the most beneficial results, the adrenalin must be administered early, repeated as necessary, in doses of five to ten minims, rather than in large single doses. Rarely, it is necessary to use adrenalin intravenously. Other drugs used are atropine, morphine, heroine, cocaine, nitrites, iodides, benzyl-benzoate, and the inhaling powders with stramonium leaves as a base. The complications accompanying cases of long duration, such as chronic bronchitis and emphysema, are often benefited by the use of autogenous sputum vaccines. The foci of infection, such as diseased sinuses and tonsils and carious teeth, have to be treated independently of the asthmatic condition, and the patient is often greatly benefited by prompt and thorough attention to these defects.

A word or two might be said here of climate. Except for the accidental absence of a causal factor in the asthmatic condition, climate *per se*, has only a limited value, in so far as it may benefit an accompanying bronchitis and emphysema. The rational treatment of asthma, however, is specific, consisting in the determination of the primary causal factor, its removal, and the therapeutic injections of extracts of the offending proteins or other substances.

The special diagnosis is made by two or more of the following four cardinal methods:

I. Contact—Symptoms of asthma following contact with a protein or other substance. (For example, a little girl who had an asthmatic attack every time she played with a cat).

II. Removal.—Symptoms of asthma disappearing upon removal of offending protein or other substance. (For example, asthma disappearing when rabbit hair pillow was removed from home.)

---

*From the Department of Bacteriology and Immunology, Division f Immunology in Cornell University Medical College, and the First Medical Division of the New York Hospital. Read before the New York Physicians' Association, March 29, 1922.

Copyright, 1923, by A. R. Elliott Publishing Company.

III. Diagnostic injections.—Symptoms of asthma produced by injections of a small amount of extract of suspected substance as, *e. g.*, 0.01 cc. of horse serum or 0.01 c.c. of ragweed pollen extract.

IV. Therapeutic injections.—Symptoms of asthma disappearing after injections of extracts of the offending substance. (For example, ragweed asthma disappearing after a few injections of ragweed pollen extract.)

The means at our disposal for the determination of the specific causal factor are 1, a careful and thorough history, and 2, the skin tests.

In obtaining the history, special inquiry is made as follows:

1. *Family history of hypersensitiveness.*—Cooke and Vander Veer (5) were the first to show that heredity played an important part in this condition.

2. *Occupation.*—The occupation of the patient himself or of other members of the family is ascertained. An illustration of the importance of occupation is seen in the case of a longshoreman, who changed his occupation to that of a porter in a department store. His duties were to sweep the floors. Within a week he had violent attacks of asthma. He was found to be sensitive to sachet powders, and upon resuming his former occupation his attacks promptly ceased. Another case that may be cited is of a lady whose attacks occurred with the return of her husband from work. Investigation showed that he was a furrier, working with rabbit skins, and that his asthmatic wife was sensitive to rabbit dander.

3. *The attacks.*—Inquiry is made as to their frequency; seasonal variation if any; time of occurrence, day or night; relationship to food; proximity to animals or plants, bedding, surroundings, etc. Did the attack follow infection, serum injection, change of diet, change in occupation, change in environment?

In determining the specific etiological factor in asthma, the skin test is the foundation of our diagnosis and therapy. It is common knowledge that the skin almost always carries cells hypersensitive to the same substance that affects the bronchial mucous membrane. We, therefore, happily have a most excellent means for specific diagnosis.

There are two methods of testing the skin; the scratch method, introduced by Schloss (6), and the intradermal method, introduced by Cooke (3). In the *Journal of Immunology* (7) a detailed comparison of the two methods appears. There can be no question that the intradermal method used by Cooke and his school is by far the more accurate. The materials used in the skin tests were also compared, in a commercial preparation in powder form and a liquid preparation made by Dr. Arthur F. Coca, in the laboratories of the New York Hospital, standardized by nitrogen content. The methods of preparation of these test materials will be found in the same journal (8).

The superiority of the liquid preparation by the intradermal method over the dry scratch method may be summed up as follows:

1. The intradermal tests are easier to do.
2. Less time required to perform the intradermal tests.
3. The intradermal tests are more convenient, the same preparation being used for diagnosis and for treatment.
4. The intradermal method has a greater diagnostic accuracy.

There are two classes of substances used for testing the skin; those that are ingested and those that are brought in direct contact with the bronchial mucous membrane, termed the inhalant group. Of the two, the inhalant group is by far the more frequent offender in asthma, being responsible for about ninety-seven per cent. of the diagnosed cases. The inhalants are: the feather preparation—chicken, duck and goose epithelium; the animal emanations—cat, dog, horse, rabbit, sheep and goat, etc.; the pollens—ragweed, timothy, etc.; the sachets—orris, cornmeal, rice bran, cornstarch, etc.; dusts—house dusts and occupational dusts; tobacco, the insect powders, wheat and many others. The foods cover the entire dietary list—fish, meat, vegetables, fruits, etc.

One one hundredth of a c.c. of each extract of these materials is injected into the skin of the outer surface of the arm forming an elevation of two to three mm. (one eighth inch) in diameter. A tuberculin syringe, graduated in hundredths, and a twenty-six gauge needle are used. Readings are made in five to ten minutes, and positive reactions are determined by the formation of a wheal with an area of erythema surrounding it. To be of diagnostic significance the wheal must be over 0.5 cm. in diameter, and show pseudopod formation. Positive reactions must always be confirmed on later tests with the same substance.

Delayed reactions may occur in twelve to twenty-four hours after the test, manifested by a zone of hyperemia which may extend from one half to four or five inches in diameter. The exact clinical significance of delayed reactions cannot be definitely stated at the present time, but enough cases occur where clinical history of trouble bears out the tests to warrant us in excluding from diet any foods (for delayed reactions occur almost entirely with food extracts) which show such reaction.

Patients are tested with extracts of the inhalants and the principal foods as a routine measure. About ten to twelve tests are made at a sitting, the exact number depending on the patient's susceptibility. Children and patients with histories of violent attacks are tested very slowly, with the use of but few tests and weak solutions of extracts. Use may also be made of the conjunctiva for testing sensitiveness, with small amounts of extracts being instilled into the eye. A positive reaction is manifested by itching and palpebral and ocular conjunctival injection.

In the few cases, where the skin reaction is negative and the history is strongly suggestive of a specific factor, a small amount of the extract of the substance may be injected subcutaneously or the food may be eaten directly, occasionally evoking mild attacks of asthma. This may be called the direct method. Therefore, in order to undertake the rational treatment of asthma, the correct diagnosis is essential and both the history and skin tests should point to the same etiological factors.

Treatment in the sensitive cases involves: 1. The removal of the offending substance; for example, the removal of feathers from the bedroom, if a person is hypersensitive to feathers. 2. Injections of extracts of the substance to which the patient is hypersensitive, beginning with minute doses, increasing every five to seven days as the case may require, until the person is free from symptoms. If the symptoms still persist, it means that some other etiological factor has been overlooked.

Treatment can be illustrated by a few specific cases:

CASE I.—J. R. O., office clerk, aged twenty-eight, married, applied for treatment on January 18, 1921. He gave a history of having had asthma for two years, the attacks occurring weekly, and lasting from one to twenty-four hours. The patient had a cat and dog at home. He was worse at night. Skin tests showed him to be sensitive to chicken epithelium, house dust, beef, fish and bananas. He was ordered to get rid of his feathers, to sleep on a silk floss pillow and to have his bedroom thoroughly cleaned of dust and kept so. He was ordered to omit beef, fish and bananas from his diet. Injections of chicken epithelium 0.05 c.c. strength .43 mg. of N to 1.0 c.c. were started, the doses being increased weekly until 0.8 c.c. was given. He began to improve almost immediately and had been free from all symptoms for over a year. During the treatment he gained fourteen pounds in three months.

CASE II.—E. C., aged twenty-one, single, bookkeeper, applied for treatment January 27, 1922, with a history of having had asthma for two years, the attacks at first occuring weekly and lasting a day or more. His attacks occurred both day and night, and for five weeks prior to the consultation his attacks were continuous, requiring administration of morphine and adrenalin. He had a complicating bronchitis. Physically, he was markedly anemic, and showed defects of the nose and throat. Skin tests showed him to be sensitive to feathers, goat dander, house dust, cauliflower, tea and salmon. Goat hair was found in his home and removed. He was started with injections of goat dander one twentieth c.c., also house dust one tenth c.c., until he received one c.c. of each two months later. He was free from all symptoms within one week of the first injection and gained seven and one half pounds in the first month.

CASE III.—L. F., aged nine years, was seen first on January 20, 1921. She had had asthma and bronchitis since the age of two. Attacks occurred every few weeks, and were worse at night; the tonsils and adenoids had been removed a year ago. The patient was found by skin tests to be sensitive to cat, oatmeal, and house dust. Treatment began with injections of extract of cat epithelium, strength .6 mg. of N to 1.0 c.c., first dose, .005 cat epithelium to final dose of .3 c.c. All symptoms disappeared within one month, and there has been no recurrence of attacks of asthma since.

CASE IV.—M. E., aged eight years, was seen first on October 16, 1921. He had bad attacks of asthma every month, lasting three to four days, for seven years, with nightly dyspnea. The patient was found by skin tests to be sensitive to rabbit epithelium and dust. Rabbit hair pillows were found in his home and removed. Treated with rabbit epithelium .005 strength .6 mg. N to one c.c., until eight tenths c.c. was given. Pillows removed from home, symptoms ceased almost immediately, and he has been absolutely free from all symptoms for over six months. He gained ten pounds in the first two months of treatment.

CASE V.—I. S., aged eight years, was presented for treatment on February 1, 1921. He gave a history of having had asthma for four years, attacks occurring at monthly intervals, lasting three to four days. He had nightly dyspnea with attacks of vomiting and wheezing on eating eggs. His tests showed sensitivity to rabbit dander, cabbage, carrots, celery, green peppers, chicken meat, salmon, ovomucoid and egg albumen.

His tonsils and adenoids were removed at the age of two and one half years. His diet was restricted to the omission of the foods mentioned above and the rabbit hair pillow found at his home was removed. Treatment began with injections of rabbit epithelium 0.05 c.c., strength, 0.6 mg. N to 1 c.c., doses increasing every week until .9 c.c. was given. All his symptoms ceased within ten days, and he has had no attacks since.

Some cases require injections of more than one substance. Foods can be eliminated, but inhalants not so readily. A patient may rid his home of his cat and dog, to which he may be sensitive, but the house dust will still contain the dust of these animals for some time. Hence, it is necessary to treat such cases with therapeutic injections of these extracts. The particular extract to use must depend on the particular case. Very sensitive people should be started with a very minute dose, increasing very slowly, watching for local or general effects of each injection.

Great care must be exercised in treating people who give a history of marked paroxysms. The nonsensitive cases, comprising about twenty per cent. of all, are treated symptomatically. These patients are nonsensitive, only in the sense that at the present time we are not able to ascertain the substance to which they may react. Future experience will most probably reduce this percentage.

All cases of asthma, however, irrespective of cause, should follow a few general rules:

1. Patients should sleep alone in a room. The walls of the room should be painted instead of papered and be free from rugs, curtains, and furniture generally. An army cot with some washable blankets is ideal. A small washable floor rug may be allowed. Mattress and pillows should be made preferably of sterilized horse hair or silk floss.
2. The room should be thoroughly cleaned and kept so.
3. Concerning diet, patients must not overload their stomachs. They should eat five to six times a day, in small amounts, rather than three large meals; the heaviest meal should be eaten at noon.
4. Constipation must be corrected.
5. Patients must not overexcite themselves, must avoid haste, walk slowly, stopping occasionally.

These ordinary, sensible, hygienic rules are important contributing factors in minimizing the intensity and even the frequency of the patient's attacks.

To illustrate the types of asthma one meets with respect to etiological factors, the following one hundred tested cases may be considered.

100 CASES OF ASTHMA.

Sensitive, 83.
  41 had chronic bronchitis and emphysema.
  3 had pulmonary tuberculosis.
  39 were uncomplicated.
Nonsensitive, 17.
Sensitive, 83.

Dust—including special	47
Chicken epithelium	21
Sachets (orris, rice, etc.)	20
Cat epithelium	14
Ragweed	11
Rabbit epithelium	10
Duck epithelium	8
Goose epithelium	2
Dog epithelium	2
Cotton	2
Timothy	1
Goat epithelium	1
Tobacco	1
Total	140

In conclusion, there are a few essential facts that must be emphasized.

CONCLUSION.

1. Asthma is an allergic not an anaphylactic manifestation.
2. The causative factor in asthma is ascertained in a large percentage of cases and in these cases satisfactory results are obtained by the methods outlined above.
3. By skin tests we can determine potential hypersensitiveness.
4. The intradermal method of performing the skin tests is the method of choice because of its greater diagnostic accuracy.
5. Positive skin tests must be borne out by history, to establish suspected substances as etiological factors.
6. Eighty per cent. of cases give a positive skin test.
7. Of these about ninety-seven per cent. in adults and ninety-five per cent. in children are due to inhalants.
8. A small percentage of cases are due to food proteins.
9. The treatment of asthma is specific and consists of 1, removal of offending substances, and 2, therapeutic injections of extracts of offending substances.

Physical Therapeutics

By J. MADISON TAYLOR, A.B., M.D.,
Philadelphia,
Professor of Physical Therapeutics and Dietetics, Medical Department, Temple University.

The American Medical Association recommends that instruction be given in medical schools in the use of remedial measures other than by pharmaceuticals, and includes dietetics. The objectives are, so they seem to me, the maintenance and restoration of balance between energies and structures. The process should be a continuous clinical performance of diagnosis and of treatment, to overcome defective or morbid conditions as they appear urgent, or as they come to be revealed in their nature and extent.

These readaptative agencies may include any or all reliable measures or instrumentalities applied from the outside, and also those initiated and guided from within, through volition. They are compounded of scientific elaborations of the best in the resources of nursing, of home or simple remedial measures, of personal hygiene, and of whatsoever modalities of motion are calculated to achieve poise in structures, to release them from positions of disadvantage, and to replace them in positions of advantage, in order to expedite económic functioning. The enterprise may be called orthokinetic therapeutics, a readaptation through some modality of motion.

They consist of, first, things done upon the individual—induced motion—such as manipulation, replacement, pressure, counterpressure, support of fixation in order to place parts in positions of advantage, also of heat, cold, light, electricity, rays and such other mechanical instrumentalities as shall prove most efficient in the particular instance.

Second, such things as can and should be done by the individual through the voluntary use of performance of his motor parts, whether guided from without or initiated from within, as are best calculated to restore motor function. The aim would seem to be a reestablishment of structure and the harmonious working of the whole organism. This second objective is coming to be appreciated as of equal or superior efficacy to the first.

Induced forms of motion may include: applications of power from without, beginning with the hand as an instrument of convenience, intelligence, and precision, through socalled manipulation, coadaptation, support, also through appraising and suggesting, partly through touch perception, gentle pressures, tactile awareness of conditions as found, also of effects of harmful conditions, deviations or alterations in surface and deeper structures, in changes in sensitiveness, in resistance, in tone—overtone or undertone. Through the tactile corpuscles can be exerted a nice apperception and interpretation through muscle sense (kinesthesis) and the determination of capabilities for response, through directing economic selfadjustment, through reducing prodigal expenditures of energy, and enhancing the power of weakened energies, all making for a state of poise, of balance, of harmonious movement from zero or rest to maximum, by increments or decrements of effort or volition.

The directing self becoming out of gear—as it frequently does—demands employment as required in connection with other measures, and is of paramount importance. Occasionally all that is needed in the case is to reestablish harmonious interaction between psyche and soma, to secure efficient adaptation and to restitute capabilities. Disability, even decrepitude, is often the effect of this conflict or imbalance between psyche and soma.

Thus the purpose is to bring about complete harmony between structures and inherent, impelling, guiding or restraining forces. These forces include those for defense, for construction, for reconstruction, and for reestablishment. They demand for their integrity expenditures of energy in accord with the then (momentary) state of volition and group structures and in accord with other circumstances. They become modified profoundly by fluctuating states of emotion—commotion—by the persistence of primal impulses, instincts, complexes, feeling reactions, all down the line of phylogeny. These confusions flare out often unaccountably on coming in contact, or in conflict, with a bewildering array of ultracomplex, often unnatural, conditions and obstructions. Hence these trends or tropisms or instincts must become understood, if possible; at least they must be reckoned with and allowed for.

Some familiarity is desirable for the clinician with the various instrumentalities, devices, and also of proficiencies in the use of the hand as adaptator or adjustor of action patterns in energies, latent, depressed or overacting—to the neuromuscular and other organic mechanisms.

The chief reason why physical therapeutics have failed to meet with the interest and confidence they deserve, it seems to me, is that so many of the instrumentalities used have been exploited in such mysterious guises, forms and elaborations, as to discourage their adoption by those who are either less mechanically minded, or whose familarity with biophysics or the associated sciences of electrology, röntgenology, or radiology, is too small or inadequate to afford confidence in their employment.

This hesitation is well founded in the main, since an insufficient knowledge of those principles leads to futilities or to harmful, or at least undesirable effects. Now that so much well verified knowledge and experience is available as to the value of active movements, these now form an enormous group of clinical resources coming steadily into confidence, and will enable successful issues to be achieved beyond any grounds or belief prevailing a few years ago. So of the simpler, homlier, applications of the nursing art and of socalled home or simple remedies. These have now become capable of alone doing more than most of the specific medications of fifty or a hundred years ago. They may be visualized as amplified measures for convalescent economies—whether from acute or protracted states. The effects of disease or injury, especially of chronic processes, resemble an obstacle race—each obstruction should be removed in order to restore, as far as possible, normal conditions.

The resources of physical therapeutics may be further divided into those which are exhibited chiefly on the periphery and those which are applied to structures most near to centres, spinal or sympathetic, or subcentres, through metameres and the lines of innervation through ganglia.

Most of the more graphic, impressive and mysterious among the modalities of electricity, röntgenology, radiology, etc., reach only, or chiefly, surface structures. Some can now be shrewdly guided so as to drive deep into structures, as e. g., in diathermy. So of röntgen rays and radium, which are now becoming to react with precision and to do what is wanted with the minimum of byeffects.

Let stimuli—expended at or near the surfaces or on the periphery—be as forceful and efficient as they may, still they are merely partial and superficial in comparison with mechanistic forces exerted upon or near centres, subcentres, upon nerve emergencies or nerves in continuity.

Effects desirable and obtainable through pressures, impacts, or vibrations or tractions upon or near the centres, are as yet little known, and less appreciated. When they come to be studied with the same exactitude as those applied to the periphery, their vastly greater, more direct reactions will cause them to become more generally employed. As to choice, "let each man at arms use that weapon best fitted to his hand."

Many means are now available for affording relief to disorders or their effects, direct and indirect, through readjustments of position and attitude, restoring interrelationships of organs and of supporting structures. Position or posture is the sum of the effects of adaptation in accord with makeup, or conformation, many of which are often faulty; attitude is the sum of the assumed adaptations through habit or in accord with local peculiarities or weaknesses, as of the static, locomotive, or supporting structures. These deserve careful appraisement and correction. There follows, then, greater economies of functioning, as the respiratory, digestive, genitourinary, circulatory, vasomotor, visceromotor, pilomotor functions.

Some faults of interrelationship can be corrected by induced movements, manipulation, readaptation, as of the abdominal viscera; others can be restituted through carefully directed and guided voluntary movements, whereby better habits of attitude can be learned, and above all practised, till they are radically overcome. One form of disorder is common to most humans, viz., inadequacy of colon emptying, whether there be hypertonic or hypotonic constipation or a delayed peristalsis with prompt, even too frequent, evacuation of the lower bowel. The desideratum is restored intestinal tone, a motor adequacy throughout. The defect may be in the external abdominal walls, especially the thoracic or pelvic diaphragm, or in other associated muscles, as of the psoas, quadratus lumborum, iliaci, etc. The cure is twofold, 1, induced movements upon the disordered centres, and 2, better positions of advantage to function while at stool. So also of parturition, a normal attitude is more economic and safe. (Prompt obedience to the impulse.)

In short, the scientific adaptation of many homely principles of personal hygiene often prove quite sufficient to restore impeded function. Nature has supplied us with no end of resources which, when used judiciously, will maintain health or restore health. It is up to each of us to recognize their efficiency and make faithful use of them. "Let the punishment (or accomplishment) fit the *time*" and occasion, or obvious need. The economic use of our endowments should be competent to so subserve and conserve our needs as to reduce or do away with almost all (drug) artificialities. This it is the great purpose of physical therapeutics.

One word about poise, balance, harmony, as the essential condition for health or repair. Body commotions are due largely to emotional imbalance. This tends to cause irregularities in force transmutation and application; hence occur some form of tremor, ataxia, explosion, or cramp. The main desideratum of repair, restoration, is equilibration. In order to secure this poise, my experience gives me confidence in teaching the muscles to work as well in the negative, as in the active, phase; that is, when conscious power is withdrawn to come to complete equilibrium or rest.

By inducing conscious control of the limb or muscle group, by graduated increments of force from zero to maximum, say two or three times, then by concentrating attention on the withdrawal of energies, akinesia, there can be established a complete harmony or poise between movements and thus restore use. Thus, a state of consciously controlled negation, or inhibition, or rest, becomes habitual. Then any motion, whether induced or initiated, produces superior effects.

Three graphic divisions or fields of operation in physical therapeutics, which often overlap and supplement each other, are:

1. The object of constructive therapy is to enhance the powers of an individual who is presumably normal, of any age, but below par and designed to raise the coefficient of efficiency in structures through improved nutrition and performance of function, for one in whom there are constitutional or energy inadequacies, adynamias, often aggravated by poor nutrition in infancy, by neglect, disuse, misuse or abuse of endowments, shown by impaired heat making or heat regulating mechanisms, defective motor tone or other malfunctioning. Remedies include regulation of diet and body habits, also conscious control of grouped or associated structures as of the neck, the shoulder girdle, thoracic, truncal or pelvic girdle, and their reciprocal relationships.

Also harmonizing of the reflex circuits and neuromuscular mechanisms where there are found commotions in the tone of structures of the contained viscera, which need repositioning and completion of the action and excursus of organs which are out of normal adjustment through developmental faults or neglect, e. g., pulmonary structures, diaphragm (the thoracic and pelvic), readapting altered states of tone in major or gross structures, also in the bodies of the organs, hollow or tubular, e. g., the respiratory, digestive, cardiovascular, genitourinary, and of the intraabdominal pressures.

2. Reconstructive: The subject being of any age but in whom anomalies of structure or tone have been acquired, over or undertone or abnormalities in sustained tone or balance due to effects of injury, or disease, or after operation, or due to metabolic or other causes, leading to deformation, decrepitude or inequalities; to afford release from limitations, from contractures, adhesions, as in partial paralysis, whether of central causation or due to injury, undue compressions, or to interferences in any way. The main objective is to prevent deformity and to stimulate movement. The barometer of permissible movement is always pain.

Getting rid of offending parts or useless or harmful tissues, local areas which require modifications or removal, or for readaptation of supplemental or accessory parts when they have been removed and where there is need, and by reinforcement, substitution, compensation, or where local support or fixation is needed until the parts are able to again perform full function in accord with design.

Among the means often required are readaptations of the creature to new and favorable environment, as of climate, temperature range, elevated or level ground, mountains or seashore, of special dryness or moisture and the like. The effects of the sun, of graduated exposure, socalled nature cures, heliotherapy; and of contrasts of heat and cold. Also thorough cleansing measures, outside and inside, release from collections of toxic wastes, e. g., colon irrigation and restitution of organs in situation and tone. Many of these conditions are similar in their nature and aims to those in class 1, requiring developmental assistance and a return of parts to positions of advantage in order to regain opportunities for functional competence and harmonious interaction.

3. Remediative: The application of modalities of dynamic or available forces, graduation of powerful exogenous energies, such as thermotherapy, heat and cold, or alternations of heat and cold, contrasts of warmth or coolness, through the media of water or air, e. g., balneotherapy, hydrotherapy, hydrology, superheated air, of sun rays, heliotherapy, etc.

These include corrective manipulations, induced movements applied to gross structures, limbs, joints, viscera, especially to the back, that being the site of many reflex effects of disorders, of effects of irritations, infections, not only of septic foci capable of radical removal by surgical measures, but also of their obstinate and recalcitrant aftereffects. Also traction, pressure, counterpressure, support, fixation, immobilization, etc., to be followed at once by voluntary movements of the impaired muscles.

4. Composite, grouped, or systematized, therapeutics, including spa treatments, "Kurs," sanitarium methods, "rest cure," various associated or mutually supplemental measures, one designed to reinforce the other as recognized to be of proved efficacy in overcoming obstinate, recalcitrant conditions, maladjustments, deformations, decrepitudes, of both body and emotions which have become reduced to states of cellular or structural confusions, retardations, deteriorations in selfguiding mechanisms.

The Quinine Test in Hyperthyroidism: Second Report

By ISRAEL BRAM, M.D.,
Philadelphia,
Instructor in Clinical Medicine, Jefferson Medical College.

The use of tests in the diagnosis of hyperthyroidism is both laudable and otherwise. While laboratory tests are a valuable addition to diagnostic methods, they not uncommonly mislead in the final analysis of the case. The more apparently dependable the test, the more will a number of busy practitioners be prone to minimize the value of their own clinical experiences, permitting their senses to become obtunded. Laboratory tests serve their highest purpose when employed as supplements to the diagnosis deducted from the conscientious use of the senses of the experienced clinician. Thus a test may confirm diagnosis. It is especially in hyperthyroidism that tests *per se* should be taken with a grain of salt, for the diagnosis of thyroid hyperfunction is perhaps the most elusive in the practice of medicine, depending largely upon the experience of the clinician.

The real confirmative value of a diagnostic test in hyperthyroidism (the same may be said of almost any diagnostic test) depends upon how small is the percentage of error associated with the performance of the test. Of the twenty or more tests described in diagnosis of hyperthyroidism, the most commonly employed are the Goetsch adrenalin test and the basal metabolism test. We are able, at this time, to state that neither is devoid of a considerable percentage of error.

THE ADRENALIN TEST.

The value of the Goetsch test depends upon two facts: first, the hypersensitiveness of the subject to hypodermic injections of adrenalin; and, secondly, an increase of symptoms in positive subjects. Hypersensitiveness to adrenalin injections is seen in a percentage of normal persons, in subjects of effort syndrome, organic heart disease, convalescence from acute infections, and in a large number of other conditions. This has been the experience of others (1 and 2) as well as my own. Moreover, though in most instances of thyroid hyperactivity the test proves positive, it is negative in a percentage of undoubted cases of this affection. But aside from the large margin of error of the adrenalin test in the diagnosis of hyperthyroidism, it must be stated that any test which depends for its results upon the whipping up of symptoms is inconsistent with the best interests of the patient.

BASAL METABOLISM TEST.

Basal metabolism observation indicates the degree above normal of catabolism going on in the body. Though the occurrence of a distinct plus reading is fairly constant in thyroid hyperactivity, there are many other conditions, eminently pituitary disease, diabetes mellitus, nephritis, myocarditis, chronic intoxications, the fevers, and even some subjects apparently normal, in which a high plus basal metabolism is observed. There is still a greater source of error in basal metabolism observation, namely the lack of expert technicians. Jones (3), in a recent article, has cleared the vision of those interested in this work. He concludes that there are three widely different sources of error in calorimetric determinations: 1, the test subject, though in normal health, may have a metabolic rate varying several degrees, and who may cooperate irregularly or not at all in the performance of the test; 2, the technician, who must execute many details and observations besides those pertaining directly to the manipulation of the instrument, and, 3, the apparatus itself, which may introduce error, perhaps consistent, perhaps variable, because of its mechanical defects unknown to the operator. In 1920, Jones, while testing his own apparatus, made comparisons of its results with those of apparatus of other makes in nearby hospitals and laboratories, and it was then that he discovered the most noteworthy, not to say startling, errors committed in metabolic determinations. For example, in a normal test subject, the metabolic rate was seen to vary from minus 17 to plus 90, through various errors, all of which were discovered to be classifiable in the above mentioned groups. On subsequent occasions Jones found this deplorable state of affairs to exist throughout all parts of the country, and aptly states that "any technician who feels that his own results are an exception to this, should see to his own technic in securing normal readings on known normal subjects before offering challenge to the proposition." On over a hundred different occasions Jones witnessed the beginning technic of over a hundred clinicians or their technicians. Not one of them, during their first attempts, came anywhere near the proper handling of the apparatus or of the subject during the period of testing, and it is a constant wonder to him that suits for malpractice are not the rule rather than the exception through the abuse of this most valuable diagnostic aid. For example, on one occasion the technician reported a plus 8 per cent. reading on a suspected hyperthyroid patient. The subject was dismissed as a neuropath. Four months later the physician, convinced that some error in the test had been made, ordered the technician to make a second test. This time the reading was plus 58 per cent. Soon it was discovered that because of a reading of three minutes and fifty-two seconds, the rate as determined previously should have been reported as plus 35 per cent. instead of plus 8 per cent. Now, however, the patient was so much worse that radical operation performed two weeks later eventuated fatally. On another occasion Jones observed a patient nearly asphyxiated during the course of the test because a tank of gas supposedly oxygen but containing nitrous oxide was used. Furthermore, the patient's viewpoint must also be taken into account. I have observed in a male subject of exophthalmic goitre a loss of five pounds in weight during a three days' stay at the hospital for metabolic tests, the patient remarking: "The cure is worse than the disease." I have found basal metabolic observations of comparatively little use in diagnosis. Its real function in this disease is to check up results of treatment. Just as the thermometer tells us that the course of a fever is at an end and the patient is convalescent, so basal metabolic observations when properly taken inform us that the excessive burning down processes in the patient's tissues have calmed down and metabolism is stabilized, and that the patient is on the road to recovery.

THE QUININE TEST.

In a previous communication (4) I reported my deductions from a study of 160 cases in which the relative immunity in subjects of hyperthyroidism to cinchonism was the principle of a test designated the quinine test in the diagnosis of thyroid hyperactivity. It was emphasized that subjects of thyrotoxemia are exceptionally tolerant to the physiological effects of quinine during the course of the disease and for a long time after recovery, and that this tolerance practically amounts to an immunity. Though no ample reason was advanced to explain this phenomenon, it was suggested that possibly the thyroid toxin in the blood exerts a neutralizing or modifying influence on the quinine, depriving the latter of the potentialities for producing cinchonism; the body having attained an immunity to quinine during the period of its administraton in the course of the disease, still retains this immunity for an indefinite period of time following recovery. A person taking forty grains of quinine daily with impunity is not necessarily suffering with hyperthyroidism, but proves to be relatively immune to quinine. As previously implied, the value of any test depends upon how small a percentage of error must be charged up against it. The percentage of error in the performance of the quinine test depends upon the number of people met with who are not suffering with hyperthyroidism but who are just as insusceptible to cinchonism. This percentage is much smaller than that met with in the performance of the Goetsch test (subjects of adrenalin hypersensitiveness not suffering with hyperthyroidism), and to be conservative, is at least as small as that of the metabolic observations in the diagnosis of this affection (subjects of high basal metabolism not suffering with hyperthyroidism). Very rarely do we meet with normal persons who can take more than ten or twenty grains of quinine without symptoms. The peculiar tolerance to quinine by sufferers from malaria and from such febrile conditions as pneumonia, the acute tonsillar diseases and other infectious processes, must not be construed as a state of natural immunity from the effects of the drug, but as a temporarily altered condition of the bodily reactions, to return to normal on the recovery of the patient. These instances of tolerance are, of course, easily determined and need not detract from the reliability of the quinine test in hyperthyroidism.

The technic of the test is simple, and, as implied, depends upon the immunity of subjects of hyperactive thyroid to the untoward effects of quinine administered in moderately large doses. The patient is given a dozen capsules, each containing ten grains of the hydrobromide of quinine, with instructions to take one capsule four times a day, to be washed down by an ample quantity of lukewarm water, an hour or two after meals and at bedtime. By the time thirty, forty, or fifty grains have been taken by persons whose thyroid function is not excessive, there develops a sense of fullness in the head, impaired hearing with tinnitus, often dizziness and headache, and occasionally a feeling of slight gastric and bladder discomfort. Persons possessing a degree of susceptibility or idiosyncrasy will experience these symptoms after the first or second capsule; while those to a degree tolerant may not complain until sixty to one hundred grains have been taken. In the presence of a hyperactive thyroid, no symptoms develop from the daily administration of quinine hydrobromide even if given during a period of weeks or months; on the contrary, improvement in the syndrome is frequently observed. In these patients, though gastric disturbances may constitute an element in the primary complaints, the administration of this dosage is apt only occasionally to aggravate slightly the gastric condition. If combined with proper gastric sedatives, however, this objection is overcome.

The hydrobromide is employed because it is the most acceptable of all the quinine salts and may be handled in larger doses without producing extreme discomfort in a patient whose thyroid gland does not functionate excessively. Also, the effects of this drug in negative patients wear off more promptly than with other forms of quinine. In the series of cases mentioned, none of the untoward symptoms experienced by nonhyperthyroid patients persisted beyond several days after the discontinuance of the drug. After my first report numerous opinions were brought to my attention on the use of the quinine test of which the following are noteworthy: Sainton and Schulman (5), of Paris, basing their study upon ten cases, conclude that the test is inconclusive and should be accepted with reservations. It must be remarked, however, that no test can be regarded as conclusive without reservations on the strength of observations limited to ten cases.

Pfahler (6), of Philadelphia, has employed the test both on controls and patients, and reports his observations as follows: "The quinine-hydrobromide test, recommended by Dr. Bram, seems to have considerable value, and I believe can be used without harm. I have used it in some instances in which the diagnosis was undoubted, and in some cases in which the diagnosis was doubtful. The test seemed to give me satisfactory results. I first tried the test on myself and my associates, and then used it on patients. . . . In the normal person there will be a pronounced cinchonism after the administration of from two to six or eight doses, but the hyperthyroid patient can take this continuously for weeks."

Since my primary report on this test in 1920, I have employed it in an additional three hundred cases, with a number of controls. I have been able amply to confirm its virtues as an asset in the diagnosis of hyperthyroidism, and have found it not only associated with a comparatively small percentage of error (approximately seven per cent.) but practically devoid of harmful effects in positive subjects.

The quinine test, when positive, confirms the diagnosis of hyperthyroidism, but does not distinguish between toxic adenoma and Graves's disease. The test is of marked value in differentiating hyperthyroidism from the following, in each of which the test is negative:

1. Simple or nontoxic goitre (with or without psychical tachycardia).

2. Mechanical goitre heart; a state of heart hurry and disturbance due not to thyroid intoxication, but to mechanical cardiac embarrassment because of pressure from an intrathoracic goitre.
3. Incipient pulmonary tuberculosis.
4. Neurasthenia, hysteria, nervous indigestion.
5. Paroxysmal tachycardia.
6. Effort syndrome.
7. Diabetes mellitus.

There are a few other conditions occasionally confused with hyperthyroidism, in which the test may be employed with advantage. Finally, the quinine test is highly serviceable in arriving at a diagnosis in those instances of Graves's disease in which both goitre and exophthalmos are absent. In such patients a positive quinine test may be regarded as conclusive.

CONCLUSIONS.

The quinine test in the diagnosis of hyperthyroidism is associated with a negligible percentage of error; it is inexpensive; expertness in its performance is unnecessary; it is harmless to the patient; and in positive subjects it usually results in some symptomatic relief.

Typhoid Fever*

By JAMES C. SMALL, M.D.,
Philadelphia,
Bacteriologist, Philadelphia General Hospital; Assistant Professor of Bacteriology, University of Pennsylvania Graduate School of Medicine.

INTRODUCTION.

In presenting this subject, I want, first, to direct your attention to typhoid fever as a vanishing disease, since in this manner one can best emphasize that progress in medical science with references to infectious disease, which has been responsible for our modern conceptions and practices in sanitation, with all of their farreaching benefits. Sanitation under war conditions has always presented a greater problem than it has under civil conditions in times of peace. The influence of sanitation upon the incidence of infectious diseases may be studied very advantageously in the records of armies engaged in the various wars of the past century. During the Mexican War, 1846-47, twenty-two per cent. of the American regular troops died of disease, fourteen per cent. were invalidated from disease, while only five per cent. were killed in battle, or died from wounds. During the Civil War, for each man killed in battle, two died of disease. In the Franco-Prussian War, 1870-71, the French mortality from disease vastly exceeded that from battle; while the Germans lost, in round numbers, seventeen thousand in battle and fifteen thousand from disease, the first conspicuous exception to the rule that, in war more men die from disease than from gunshot wounds.

In the Spanish-American War the records show 293 deaths in battle and 3,681 from disease, a ratio of one in battle to 12.5 from disease—the worst record for any war in which our country has engaged.

Most of you can well remember the nature of the disease responsible for this black record. The most fatal were typhoid fever for the volunteer camps in the United States; malaria and dysentery for the Philippine expedition; and malaria and yellow fever for the Santiago expedition. The board appointed to investigate the typhoid fever epidemic of the military camps in the United States in 1898, threw instructive light upon the subject. In 106 regiments, according to this expert board, hardly one half of the cases of typhoid fever were diagnosed as such because the disease presented many mild and atypical forms; so that the rate of admission, which was reported as 88.55 per thousand strength, should have been 192.65. Their conclusions were that the disease was largely fly-borne, as the swarms of these pests alternated in their feeding places between the latrines and the unscreened mess tents.

During the World War from April, 1917, to November, 1919, in our forces comprising about four million men, there were 1,056 cases of typhoid fever and 156 deaths from the disease. Sanitary conditions in the instance of the men in the trenches were about as bad as one cares to imagine, hence the protection from preventive inoculation contributed enormously to the favorable record. The experience in the recent epidemic at Salem, Ohio, shows that our discharged soldiers are protected by typhoid vaccination for at least two or three years (1). Thus in the Spanish-American War, one typhoid death occurred among every seventy-one soldiers; in 1917 one typhoid death for each 7,143 civilians; and during the World War there was one typhoid death for each 26,641 American soldiers. The ninth annual report of typhoid in the large cities of the United States, published in March, 1921, shows that in fifty-seven cities, the combined populations of which represent about one fourth of our country's total population, the total number of deaths from typhoid has decreased from 4,114 in 1910 to 921 in 1920, i. e., the death rate per hundred thousand has decreased from 19.59 in 1910 to 3.52 in 1920. This report includes only cities with a population of more than a hundred thousand and does not reflect typhoid conditions in those places in which we are most interested, namely smaller cities, towns and country districts. It is pertinent to observe, however, that from 1906 to 1910 the average death per hundred thousand in twelve cities with populations of over five hundred thousand each was 25.64, while that of ten cities of one hundred thousand class was 25.34; for the same classes of cities in 1920 the rates were 3.1 and 4.76 per hundred thousand respectively. This would seem to indicate that the smaller cities are not lagging far behind in the effectiveness of their antityphoid measures.

---

*From the Bacteriological Laboratory of the Philadelphia General Hospital. Address before the Convention of the Fifth Censorial District, Pennsylvania State Medical Society, Caledonia, Pa., September, 1921.

ETIOLOGY.

A definite conception of the infectiousness and the transmission of typhoid fever from case to case was formed as early as 1856, by Budd, but it was not until 1880 that Eberth discovered in the spleen and mesenteric glands of typhoid patients coming to autopsy a bacillus, which we now know as the typhoid bacillus. Three years later Gaffky succeeded in obtaining it in pure culture. I will not go into a discussion of this bacillus, except such characters of it as directly concern us in studying the transmission of the disease. The bacillus is passed in vast numbers in the feces of patients, and also in the urine and sputum at times. It may be cultured from the rose spots. Outside the body boiling temperature kills it quickly, but freezing does not. Direct sunlight and desiccation kill it more tardily. In soil it may be live and multiply for long periods. In distilled water it may live as long as two or three months. In sewage, contaminated water, and in the feces, it tends to die out rather than multiply, because it cannot withstand the competition of the stronger growing saprophytic bacilli, especially the colon bacillus. Milk is an especially good culture medium for it. Outside the body it maintains its virulence, so that it remains ever ready to set up infection on gaining access to the body.

PATHOGENESIS.

Entrance to the body is gained almost always by way of the mouth. It is capable of withstanding passage through the stomach, and finds lodgment in the lymphoid structures of the intestines. Thence it is readily taken up into the lymph and blood channels. Its points of predilection, in addition to the lymphoid structures of the intestine, are the mesenteric lymph nodes, the gallbladder, the spleen, and later, with general septicema, the rose spots of the skin. The first four of these are usually spoken of as the sites of primary lesions of the disease. The local lesions in the intestines do not differ greatly in their progressive and healing processes from those of a localized pus infection of the skin, for example, a furuncle. There is hyperemia, edema, pressure necrosis, sloughing with ulcer formation; and later, in healing, the cicatrization in the subepithelial layers and the growing over of the epithelium. A fundamental difference is, that in the intestine, due to peristalsis and the erosion of the intestinal contents, the slough may be separated prematurely when bleeding results. Also the healing is slower because conditions of rest and cleanliness of the base of the ulcer cannot be maintained.

I will not go into the pathology in detail, nor will I discuss the symptomatology except to touch briefly on the anatomical and physiological bases of the symptoms. It is obvious that the general symptoms are much more pronounced than would be expected on the basis of the anatomical lesions in the gastro-intestinal tract. We might expect increased peristalsis, interference with the absorption of water from the large intestine, and a condition of diarrhea from the inflammatory lesions of the bowel, as occurs in amebic dysentery, for example, but not necessarily the high temperature, and the toxemia. On the contrary, the gravest cases show, at one time or another, a tendency to intestinal stasis with meteorism, which conditions indeed parallel, in their troublesomeness, the gravity of the general condition, and have come to be explained on the basis of the extreme toxemia.

What is the source of this toxemia? Does it represent abnormal absorption through the ulcerated intestinal wall? Is an inherent toxin of the infecting organism itself responsible, or is it due to an abnormal product formed by natural processes within the body directed in an unusual manner against the infecting germ, or concerned in the riddance of the tissue killed by the bacterial activity? The first may be answered in the negative by reference to cases of typhoid without intestinal lesions but yet with toxemia. The second is a factor, for it is well recognized that the typhoid bacillus contains an endotoxin. This toxin of the bacillus itself is perhaps the principal cause of the toxemia. The bacilli are destroyed in the blood stream and as their protein undergoes digestion, this endotoxin is liberated, while at the same time toxic split protein products are formed. In regard to the third question raised there is the possibility also that similar toxic split protein products may arise from the parenteral digestion of body cells killed by the activities of the infecting organism. We may regard then the toxic products of the bacillis as primarily responsible for this toxemia, and toxic protein products as secondary adjuncts.

The effects of the toxins are manifested clinically chiefly in symptoms referable to the nervous, circulatory, and the digestive systems. Thus referable to the nervous system, we have the headache, apathy, delirium, neuritis, general lack of tone in both skeletal and visceral muscles, and interference with the temperature regulating mechanism; in the circulatory system, the relative bradycardia and myocardial weakness, vasodilatation, the leucopenia and the anemia; and in the digestive system, profound disturbances in the production and in the activities of the enzymes concerned in the digestion of food, and interference with its assimilation, manifested in the anorexia, vomiting, etc.

According to our present views the fever represents a manifestation of the struggle between the infecting bacteria and their toxins, and the protective agencies of the host. The increased temperature is indicative for the most part of the increased oxidation processes attending the abnormal catabolism, as well as of the disturbances in the temperature regulating mechanism.

Obviously such local manifestations as intestinal hemorrhage, enlarged spleen, colycystitis, the rose spots, and other symptoms, are directly due the bacteria as they proliferate in the primary sites of infection, or are transported to other sites by means of the blood stream. Such complications as thrombophlebitis, chronic colycystitis with gallstone formation, otitis, periostitis, and others are referable to this same dissemination of the bacteria by the blood. Others such as bronchial pneumonia, pleuritis, pericarditis, nephritis and cystitis may be either due to the typhoid bacillus, or, in part, to other bacteria that have seized the opportunity of attacking a host debilitated by the primary infection; while such a sequella as furunculosis is due solely to the secondary invaders. The residual effects of the toxins are seen in the sequellæ —neuritis, nonsuppurative arthritis, posttyphoid psychosis, melancholia, and feeblemindedness.

The frank case of typhoid fever is recognized almost at a glance by the experienced physician. It is the younger physician of today who seeks the laboratory in the diagnosis of such cases. He has not seen typhoid. On the other hand I have seen older and experienced physicians puzzle over atypical cases in which they could do no more than suspect typhoid, and suggest other conditions which might be present, until a blood culture proved positive for typhoid.

I would not have you understand me to imply that laboratory work is not a useful adjunct in the diagnosis of typhoid fever, for it is that, and furthermore some laboratory work on typhoid patients is a necessity if as physicians we would render the best service to the community. The physician's duty does not end when he gets the patient "out of danger" but only when he complies with our present established methods to indicate that the patient himself is not a source of danger to others. I refer, of course, to determining when the patient ceases to excrete typhoid bacilli. Health boards require that three cultures of the urine and feces be negative for B. typhosus before discharging the patient. It is better to overdo than to underdo this.

The only laboratory finding which is conclusive proof that the patient has typhoid fever is the finding of Bacillus typhosus in a culture of the patient's blood. In well over ninety per cent. of patients during the first week of illness this may be obtained. The percentage decreases later since the blood tends to rid itself of the bacteria. Next in importance, diagnostically, is the culture of the feces. Even with the most heavily infected stool, it is estimated that the ratio of Bacillus typhosus to the other bacteria in the stool is as one to one hundred, so that differential media and an experienced bacteriologist are requisites in such a diagnostic procedure. Even so, repeated cultures are advisable before negative evidence becomes of much value. This is especially necessary in attempts to identify carriers, where the numbers of the bacilli excreted are relatively few. A positive stool culture identifies the patient as an active case, or as a carrier. Cultures of the urine are next in importance. These, of course, do not become positive until after the organisms have entered the blood stream, although they may continue positive after the blood stream has cleared up, due to a more tardily healing specific inflammatory focus within the genitourinary tract.

The Widal reaction ceases to be of use as a reliable diagnostic finding, since antityphoid vaccination has been practiced so extensively. The inoculation alone produces this reaction which may persist for months, and after disappearing for a time, it may again become demonstrable during the occurrence of any febrile attack. By determining the greatest dilution of a serum which will still produce agglutination of typhoid bacilli, we have a method of greater diagnostic importance. This is known as the macroscopic agglutination test, performed in small test tubes, and standardized by Dreyer—often called the Dreyer method. In typhoid fever these agglutinins may be demonstrated in the blood in about thirty-five per cent. of patients during the first week; in the second week in about eighty per cent.; and up to four weeks in from ninety-five to ninety-nine per cent. of cases. By repeated determinations of the concentration of these agglutinins in the serum of the patient during the course of the illness, they are observed to rise during the second and third weeks to high levels; whereas the agglutinins present in the blood from previous typhoid inoculation will rise only moderately with any febrile attack, other than typhoid. Thus by plotting out the curves we may arrive at a fairly reliable differential diagnosis. This method is also applicable to the paratyphoids, and in their differential diagnosis from typhoid. It was used extensively in the study of trench fever and other fevers in France as a means of ruling out typhoid and paratyphoid infections.

I should like also to emphasize the importance of blood counts. Typhoid fever gives a leucopenia from the onset. Differential leucocyte counts are less helpful, although there is a relative increase in the lymphocytes. A febrile disease with leucopenia limits the presumptive diagnosis to about four or five conditions.

PROPHYLAXIS.

The measures for the prevention of the disease may be divided into three main groups:

1. General measures directed to the protection of the entire community.
2. Special individual measures, by means of which the transmission of typhoid fever to those who come in contact with the patient is prevented.
3. Preventive inoculation, by means of which an attempt is made to render the person inoculated immune to the disease.

Before taking up the details of the methods for accomplishing prophylaxis, it will be well to summarize the principles underlying the measures to be cited. The development and the manifestations of typhoid fever are dependent on lesions in the human organism resulting from the invasion and the multiplication of the Bacillus typhosus. The growth and development of the typhoid bacillus naturally takes place in the body of the typhoid patient, and artificially in certain foodstuffs (e. g., milk) contaminated with excreta of individuals harboring the bacillus. The germs are thrown off in the feces and urine of the active case or of the carrier. It enters by the mouth of the next person in which it sets up the disease, no cycle of development in an intermediate host being necessary. The organism may live for months under proper conditions outside the body of man, a fact of importance in consideration of the immediate transmission of the disease. The principal disseminator of the germ is water. Others are milk, shellfish, green vegetables, fruit and flies.

The susceptibility to typhoid is universal, the disease being observed in all civilized countries of the earth. Young persons and adolescents principally are predisposed to the disease. Children under one year are rarely attacked, while after the fortieth year the frequency decreases. Recovery from one attack usually furnishes protection from subsequent attacks, although second attacks occur. The majority of cases occur in late summer and autumn.

GENERAL MEASURES OF PROPHYLAXIS.

Bearing in mind the above considerations, there appear two places of attack. First, adequately taking care of all the bacilli which leave the body with the excreta; and secondly, adequately protecting all things taken by the mouth from contamination with the germ. If the first could be carried out perfectly, there would be no need for measures aimed at the fulfillment of the second. Likewise if the second could be fulfilled perfectly, we might neglect the first, and still typhoid would become an unknown disease. Since neither can be done perfectly, we must aim to do both with as much perfection as possible, and herein lies the only hope of limiting the otherwise widespread dissemination of typhoid bacilli. A third possibility for blotting out typhoid remains, namely, that of rendering every person immune to infection with the organism, however widespread its dissemination may have been allowed to become. Under the latter state of affairs, typhoid bacilli would mean nothing more than does the colon bacillus under present circumstances. But this condition again can only partially be fulfilled in the prophylactic inoculation against the disease.

The difficulties with accomplishing the destruction of all the typhoid germs leaving the body lies not so much in the active clinical case of typhoid fever, but in the mild, missed cases of the disease, and in the problem of identifying and controlling the temporary and the permanent carriers of the bacilli. During the actual febrile period of the disease the excreta can be disinfected and disposed of with comparative safety so far as contact dissemination is concerned. The problem with the active case is to determine when during convalescence typhoid germs cease to be excreted, and to keep up the precautionary measures, provided it so happens that the recovered patient continues as a temporary, or more dangerous still, as a permanent carrier. Cultures of the urine and feces furnish a means of determining these points, but unfortunately cultural diagnosis is not generally available and even with it, patients are, no doubt, at times discharged, who subsequently may excrete the bacilli for varying lengths of time. Many of these carriers go unrecognized until a local epidemic of typhoid fever is traced back, only to find one of them working in a dairy, or at some occupation involving the handling and distribution of foodstuffs. In this way, year after year, we have brought to our attention very forcibly the fact, that every individual harboring typhoid bacilli is a real source of danger to the community, in that at any time he is likely to be the focal point from which arises an epidemic of the disease. The less he is suspected to harbor the organisms, the greater becomes the danger, for then precaution is thrown to the winds.

The carrier is then the greatest danger in the typhoid situation; next is the unrecognized case of typhoid; and lastly, least dangerous, is the recognized case of the disease.

Attempts at the fulfillment of our second hypothetical condition—that of preventing all things taken into the mouth from being contaminated with typhoid bearing material—involve all our modern methods of sanitation, which I need not go into in detail. Conditions in the cities, towns, and even in the villages have improved wonderfully, so that drinking water and sewage are for the most part kept separated, and so that each is so treated with chemicals, or otherwise, that it is rendered free from dangerous pathogenic bacteria. Water epidemics are growing fewer in the urban centres. In the country local outbreaks occur, and there are always some cases, undoubtedly of water origin, among vacationists returning to the cities each autumn. Dairy products, green vegetables and fruits may be contaminated from water sources, but more often through being handled by typhoid carriers, or by means of flies. The practice of the U. S. Army of having all food handlers studied by means of bacteriological examinations of the urine and feces for the detection of carriers is to be highly commended and is deserving of a more general application in civil life. According to a report of the British Committee investigating the spread of typhoid only fifteen per cent. of the cases were attributable to flies.

VACCINES IN PROPHYLAXIS.

Of all the countries engaged in the World War, Germany alone is not convinced of the efficacy of vaccines as a means of prevention of diseases of the typhoid group. For the most part the Germans used a vaccine killed by heating to 60° C., and there is no doubt that the efficacy of a vaccine is much lowered by exposure to this temperature. Later they improved their vaccines by heating only to 52 to 55°. Good results were obtained also with chloroform killed cultures. The French introduced the lipovaccines, in which the killed and dried bacteria were suspended in oil. This vaccine was also prepared in our army laboratories, and was used to some extent. It never became the authorized vaccine of the army, and its preparation has since been discontinued. It perhaps does not give quite as great a degree of protection as the saline vaccine. Its chief advantage from the army viewpoint was the single dose. Other features are, the attenuation of the toxic effects on account of the delayed absorption, and perhaps also through a partial neutralization of the toxins by the oil.

SPECIAL INDIVIDUAL MEASURES IN PROPHYLAXIS.

1. The only infective agent consists in the typhoid bacilli developing within the patient and extruded especially with the stools and urine. Contact with the patient is dangerous only insofar as there is danger of ingesting such infectious material. It, therefore, follows that patients are to be so taken care of and their discharges to be so treated that they shall not be a source of injury to others.

To overcome the dangers of contact infection, remove patients as far as possible from crowded dwellings, or from surroundings which do not permit of their proper isolation. Wherever possible patients should be sent to the hospital. If treatment at home is necessary, provision for nurses and attendants sufficiently informed in regard to the character of the infection and appreciative of its mode of transmission and prevention, should be made. All others are to be kept away from the patient.

In arranging the sick room, all unnecessary articles should be removed, especially rough woolen articles, carpets, and upholstered furniture. The room should be screened and kept free from flies.

Dejections from the patient are best received in porcelain bed pans and before being thrown into the watercloset thorough disinfection should be practiced. Chloride of lime is efficient for this purpose and is recommended because it is inexpensive and also is easy to apply. The solid may be dusted in the bottom of the bedpan before use and about a quart of a mixture of six ounces per gallon of water should be used to cover each stool, when the vessel may be covered and allowed to stand for one hour before emptying. Thorough cleansing and rinsing of the pans should be effected regularly, preferably with lysol solution. The same rigid disinfection of the urine, wash water and also remnants of food should be practiced. Sputum may more conveniently be received in paper receptacles and burned. Bed linen, body linen, etc., should be immersed in a five per cent. lysol solution before being turned over to the laundress. For the hands of the attendant a solution of one to one thousand mercury bichloride may be used. During the illness a solution of lysol in water should be used for washing floors and woodwork.

Preventive inoculation, while it should not be neglected until the appearance of typhoid, may yet well be employed in guarding others against the infection, always bearing in mind that little can be expected in the way of protection within the first two weeks after inoculation. It is here that a single injection of the lipoid vaccine may provide earlier protection than the more extended triple inoculations with the saline vaccine. The question of the socalled "negative phase" following the injections must be considered in applying preventive inoculation, so that persons with any abnormal temperature would not receive it.

TREATMENT.

Nursing is a most important factor in the treatment of typhoid fever and the physician is responsible for providing efficiency in this particular.

Perhaps the greatest advance made in the treatment of typhoid has been that pertaining to the dietetic management. Those of you who have observed typhoid patients in the days when they were starved, as well as dehydrated, will readily agree that no one single innovation in the treatment of the disease has been so conducive to the patient's comfort and well-being as that attending the introduction of the present day practices of feeding throughout the course of the illness. The principles involved in the adequate nourishment of typhoid patients are very definitely established. The protracted febrile condition requires increased food energy supply to meet the abnormally high amount of heat energy lost. Failure to supply adequate food energy to meet this loss of heat energy involves, first, the utilization of the supply of stored food energy of the body, chiefly the reserve carbohydrate and fat, but subsequently the formed body protein substances are broken down and utilized by means of the increased catabolic processes attending the febrile state. It is most important to shield the body proteins against this destruction.

The precarious local condition of the intestine, the digestive disturbances attending the toxemia, and the protracted febrile course constitute the main difficulties in applying these principles of adequate nourishment to the individual patient with typhoid. We must aim to overcome these difficulties by supplying food of high caloric value in an easily digestible and readily assimilable form. Carbohydrates, fats, and gelatinous substances meet these requirements when supplied in liquid or semisolid form. They should be given in small amounts and frequently, every two or three hours, day and night in the severe cases.

Milk deserves first mention among the actual articles of food since it supplies all the elementary food substances in a readily digestible form. Carbohydrates in the form of starchy and mucilagenous soups are very useful. Mashed potatoes well buttered or covered with meat juices are usually well received. Egg albumin water flavored with fruit juices or wines is to be highly recommended. The use of edible dried ox-blood or serum, rendered palatable and acceptable in a variety of simple preparations deserves a more general application in this country in nourishing acutely ill patients. Certain artificial foods may be especially useful at times. Alcohol serves both as a stimulant and as a source of readily available energy and may be used to great advantage in typhoid. The best drink is good cool water and it should be supplied to meet the patient's desires. Fruit juices may in part supply the fluid need, but a given flavor is likely to become distasteful very quickly, so that the flavors should be varied frequently, and they should never be urged upon the patient.

The appetite begins to return while there is still need for great caution in the choice of foods that may be allowed. It is very easy to meet the calory needs of the patient by increasing his allowances but it is more difficult to meet his craving for bulk to overcome the feeling of emptyness.

ANTIPYRETIC MEASURES IN TREATMENT.

The present conception of fever is that it is a manifestation of a useful defensive reaction on the part of the patient combating an infection, and that the increased metabolic processes attending the febrile condition may be a means of releasing the antibacterial defences more rapidly than they would otherwise be released. The wholly rational method of assisting nature in this process would reside in measures which would be efficient in ridding the patient of the infecting bacteria, or, failing in this, to provide for the neutralization of the toxins of the bacterial infection. With typhoid fever we are unable to accomplish either of these. There remains then the expedient of trying to promote the elimination of the toxins while at the same time so caring for the patient that he will always be in the best possible condition to combat the infection through his natural defences. Continued and excessively high temperatures interfere with the patient's rest, bring on exhaustion, and throw a greater load on the cardiac and respiratory mechanisms. Symptoms of restlessness, delirium, exhaustion, cardiac weakness, and respiratory embarrassment should be the indications for the employment of measures aimed at lowering temperature rather than a temperature reading above a certain degree as indicated on the thermometer.

Hydrotherapy is the most efficient form of antipyretic treatment. Water may be employed in a number of ways. Full baths at one time used extensively are being less used at present because they are cumbersome of application and since in typhoid fever the desired effects can usually be obtained by tepid or cold sponging. Accessory to these the icebag may be used to the head in cases with marked stupor and delirium. When the pulse frequency is high, some employ a small icebag over the heart.

Antipyretic drugs have little use in typhoid. They may be in full doses markedly depressent. The manifestation of this effect may tend to quiet the patient, but the end effects can scarcely be regarded as beneficial to the patient. On the other hand, with hydrotherapy, the same quieting effects on the central nervous system are accompanied by improvement of the pulse and respiration, while at the same time we have provided an efficient method to promote elimination through the skin.

I need not go into the symptomatic treatment referable to the individual organs or systems. In handling that dreaded complication, intestinal hemorrhage, there is nothing new to offer. The principles are to overcome the attendant restlessness at once with the free use of morphine, and later in case of alarming collapse to institute treatment for shock. It is well always to bear in mind that a moderate degree of collapse is nature's last resort in controlling hemorrhage so that it is not well to combat this unless very alarming cardiac weakness follows an unusually severe hemorrhage. An icebag or cold Leiter's coils are used over the abdomen, presumably with good effects. Styptics administered by mouth are naturally useless. Calcium chloride by mouth to increase the coagulability of the blood, because of slow absorption, acts too tardily to control the acute hemorrhage, but finds use where there has been manifested a tendency to bleed. More is to be expected from the intravenous administration of calcium chloride (up to five c. c. of a five per cent. solution). Administered in this way it has an opiumlike effect in allaying peristalsis and intestinal irritability, while at the same time the effect in promoting coagulation of the blood is obtained at once. Subcutaneous injections, or intermuscular injections of normal horse serum have come into much favor in combating a tendency to hemorrhage.

SPECIFIC TREATMENT OF TYPHOID.

The use of specific serums has never gained much favor on account of their doubtful therapeutic results. Vaccines have been employed extensively, first, indeed, as early as 1893 by Frankel. Frankel's favorable reports with specific vaccines in treating typhoid fever were followed almost immediately by the reports of Rumpf, who obtained good results with a vaccine composed of the Bacillus pyocyaneus. In these two instances we have the beginnings of the use of specific and of nonspecific vaccine therapy in typhoid. Following Wright's work in 1902, vaccines have come into vogue. Ichikawa in 1915 revolutionized the method of employing vaccines in treatment of acute infections, when he introduced the intravenous method of administration. He treated twenty-one typhoid patients with typhoid vaccines intravenously. Two died as the result of uncontrollable hemorrhages from the nose. Of the remaining nineteen, seventeen made immediate recoveries as far as temperature and toxic symptoms were concerned, one had a recurrence with bronchopneumonia and died, and one had a recurrence which subsided immediately after a second dose of vaccine. Gay reports that sixty-six per cent. of the patients with typhoid treated by him with intravenous vaccine were favorably influenced.

NONSPECIFIC PROTEIN TREATMENT.

Since these reports, our ideas of the specific nature of these effects have been overturned, for equally encouraging results have been obtained from a variety of nonspecific, or, socalled, foreign protein substances. Various nonspecific vaccines, peptone, secondary proteoses, deteroalbumose, milk, foreign serum, etc., are among the many substances which have been used and the remarkable thing about it all is that similar effects are produced by all. Colloidal metals have also been shown to produce like effects.

Favorable results with these methods of intravenous therapy are so prompt and striking as to be almost unbelievable. Following the injection, there is a chill lasting from fifteen to forty-five minutes, a rise of temperature which subsides to normal, or subnormal, in twelve to eighteen hours, following which the fever simply fails to return and the signs of the toxemia have disappeared, the patient appearing not unlike a malaria patient between chills. In typhoid it is conservative to say that about one fifth of the patients respond in this manner, while in a fifth more the disease terminates by short lysis.

This form of treatment is still regarded as heroic and is not to be generally advised. Its likelihood of increasing the tendency to hemorrhage alone makes it unsafe in typhoid patients. It would certainly never be employed in cases which had shown hemorrhages. It should not be employed in extremely weakened and debilitated patients, or in patients in whom the cardiac condition is such that no reserve energy is available to tide them over the period of the chill and increased temperature.

The manner of action of these substances cannot be accounted for by principles of which we at present have a definite understanding.

Theoretical explanations are: Selective stimulation of the hematopoietic organs which are believed to be the source of antibodies. High temperature is unfavorable to the establishing of an infection and perhaps to its continuance. Leucocytosis—increased phagocytosis. Mobilization of ferments—which may aid in rendering bacterial toxins nontoxic. Antiferments which have been shown to hinder bacterial growth in some instances. Physical changes in the serum. Antigen and antibody coexist; may release antibody.

The most recent development in the way of biological agents lies in the finding of a substance in the filtrates of the stools of convalescent typhoid patients which has the power of dissolving typhoid bacilli. A portion of the filtrate from stools is said to dissolve an entire broth culture of the bacteria and this dissolved culture in turn possesses the same property. In this manner, this bacteriophage, as it is called, can be carried along indefinitely. Reports are beginning to appear now on employing this substance in therapy, but no definite methods have been developed.

Physiological Effects of Static and High Frequency Currents

By FREDERIC DE KRAFT, M.D.,
New York.

In the application of electricity to the human body for the relief of various constitutional and local pathological conditions, our aim is to produce certain definite physiological responses, such as muscular contractions, removal or venous sedation of motor and sensory nerve fibres. The armamentarium required for this is quite an extensive one. It should include:

1. A large modern Holtz machine.
2. A wall plate from which is to be had the galvanic, faradic and sinusoidal current.
3. A suitable transformer for high frequency currents and for diathermy.
4. An x ray apparatus.
5. Devices for light and heat applications. A mercury vapor quartz light, or an arc light apparatus, of which the Hofman infra Ultra Rays generator is an example.
6. A vibrator.

We have placed the static machine at the head of the list for the following reasons: 1, It is the oldest electrotherapeutic apparatus. 2. The expert finds it the most flexible means of producing certain reactions.

The oldest and to this day one of the most efficient means at our command of producing a sudden perturbation in a part, together with a transitory anemia which is quickly followed by arterial hyperemia, is the static spark.

To administer this we place our patient on the insulated platform. The sliding rods are widely separated. The shepherd's crook is hooked on to the positive sliding rod, the negative side is grounded. The machine is now started. The patient is thus charged with positive electricity, the walls and sides of the room with negative electricity. A metallic ball electrode is grounded by a chain to a separate ground. With a sudden approach of this ball sparks, long or short, are withdrawn from the part to be treated. At the moment a spark strikes the patient's body, under these conditions, there is produced a sudden equilibrium of the patient's and the earth's potential. In other words, we effect a very sudden discharge of the accumulated static charge.

The result of this is evident to the observer. The sudden incidence of the spark to the bare skin of a patient produces a sharp, incisive, scarcely painful blow, a contraction of the muscles, marked spots of anemia, cutis anserina. This is quickly followed by hyperemia. In nervous persons the suddeness of the spark is apt to cause so much psychic effect as to lead the uninitiated to think that the painfulness of the procedure is great. The contrary is easily proved. Sparks are, however, painful when applied to bony protuberances.

The effects just described make sparks a valuable aid in the removal of infiltrations, the relief of muscular spasm, and the promotion of nutritional interchanges. In place of this method I have used, with satisfaction to myself and patients, a resonator discharge from a static machine for more than twenty years. This resonator consists of an inverted Tesla coil, to one end of which is attached a solenoid for the purpose of increasing the wave length.

The d'Arsonval (the primary) and the Tesla (the secondary) are insulated by very heavy insulation. This consists of a tube of mica and heavy fibre; gallon size Leyden jars are connected by the inside to the static machine, while their outside is connected to the primary of the coil. This arrangement is known as the de Kraft resonator. We have in this apparatus a means of increasing or diminishing the length of the spark at the exploders between the Leyden jars. This gives us also a means of regulating the length of the effluve, from a very short one of considerable warmth to one of great length and coolness. If the powerful static machine is run slowly the individual pulsations will recur slowly. The greater the rapidity of the machine the more rapidly the Leyden jars fill and the greater the frequency of the impulses of the pulsations. They may be made so great that no muscular response is elicited. All of the local and constitutional effects of static sparks, as previously described, may be obtained herewith to any desirable degree; and in addition we have a means of procuring rhythmical muscular contractions of any part of the body. The bipolar method is the one usually practised. A metal plate is attached to the Tesla and placed over the abdomen or back directly over the bare skin. The effluve electrode is attached to the solenoid and is moved more or less rapidly over the part to be treated.

Passing from the static spark to the static brush discharge our step may be more or less abrupt. To diminish the abruptness we must use, instead of a metallic electrode, some medium which offers resistance to the abruptness with which we endeavor to equalize the patient's and the earth's potential. A wooden stick electrode, made of maple or white wood, which is capable of absorbing moisture, is the best means of obtaining the short, hot, peppery discharges known as the sputtering brush discharge. These consist in reality of very fine sparks. Their impact causes a sensation as if hot sand were thrown onto the skin. The effect on old ulcers is very stimulating. The ozone and nitrous oxide, which are evolved during the administration, effect a glazing over of ulcers which may act as a protective covering. Friction sparks obtained by rubbing a ball electrode very rapidly over the surface of the body (preferably over the clothing of the person) have a very warming, revulsive-hyperemic effect and serve to relieve pain by reason of the decongesting and numbing effect on hypersensitive nerve endings. The resistance of the clothing and of the dry skin, which offers an almost impenetrable wall to these extremely short sparks of relatively low potential, serves us well by breaking the abruptness of the equalization of potential.

To secure the maximum physiological effect of the blue pencil brush discharge, it is necessary to have a large static machine of twenty revolving plates operating at a maximum of efficiency. To obtain this we have the sliding rods widely separated. The patient is connected to the negative side of the machine, the positive side is grounded, the electrode (de Kraft blue pencil electrode) being grounded to separate ground.

This electrode consists of a wooden shell in which asbestos is packed. It serves as a means of adding resistance to the static current, making possible a very long blue spray which is soft and unirritating. This spray consists of thousands upon thousands of fine sparks. It is very luminous and possesses to a high degree the property of ionizing the air between the electrode's metal point and the patient's skin. The blue pencil spray has pain relieving and general sedative properties of a very high order. It also produces hyperemia of the part to which it is applied.

The constitutional effects produced by it may be summarized as follows: It enhances the oxidation processes of the body as a whole. There is produced a marked sense of coolness. It has a marked stimulating effect which has been compared by some patients to that of champagne. Applied for its strictly local effects to an acutely inflamed joint, the relief from pain is often almost instantaneous. We have seen patients, who had been tortured with pain for several days, fall sound asleep within five minutes after the beginning of its application. We have seen the discoloration of a joint, the result of subcutaneous effusion of blood, the result of trauma, subside in a most surprising manner. It relieves muscular spasm more quickly than any other physical agent.

The static wave current is simply another means of utilizing the physical properties of the spark. The patient, being seated, on the insulated platform, is connected to the positive side of the static machine by means of a suitable wire to which is attached a metal electrode. The negative side is grounded. With the machine running at a suitable speed a series of sparks are allowed to pass, by opening up a gap between the balls of the sliding rods. The longer these sparks the greater the potential of the current delivered to the patient. For administering this modality to a part of the patient's body, we use sheet metal electrodes of a size and shape suitable to the condition we wish to treat. These are placed in direct contact with the bare skin. For applications to the cavities of the body, such as the rectum, prostate, uterus, suitable electrodes are utilized.

By means of this arrangement we have it in our power to charge and discharge the person on the insulated platform with impulses recurring rapidly or slowly. The density of the entering charge is governed by the size of the metallic electrode and the potential delivered. The greater the density of the current and the greater the potential the more pronounced will be the tissue contracting effect of this spark discharge.

This tissue contracting effect is of considerable use in those conditions where we wish to change the vascular tone of a part. Proper regulation of the spark discharge at the sliding rods enables us to effect in a high degree tissue drainage and relief of spasm. Too high a rate of spark discharge does not give the tissues time to recover from the stimulation. It induces fatigue. With the more moderate rate of spark discharge we aim to get periods of alternate contraction and relaxation. In this way we may improve the general metabolism and produce a marked tonic effect on the entire body.

Jenks and Clarke have shown in their Report to the American Electrotherapeutic Society in 1904 that an ordinary static machine of that period was capable of charging a condenser to eight hundred amperes and over. All of the methods we have spoken of depend for their physical effects upon the wonderful power of accumulation of static electricity, upon its ability to produce capacity discharges because of its ability to fill condensers. It is because of this that we get deeply penetrating physiologic response.

If we attach a Leyden jar to each of the prime conductors of a static machine and have the sliding rods slightly apart, the machine running at fair speed, we note the rapid passage of sparks at the sliding rods. A pair of electrodes attached to the outer coatings and held the same length apart will also show a shower of sparks. This is the basic arrangement of all high frequency currents. It is called the static induced current. By means of this we may effect marked tissue contractions at a rate of frequency dependent upon the rapidity of the revolving plates of the machine. When the generating capacity of the machine is great, the Leyden jars small and the spark gap very short, no contractions will be produced, but we may procure a numbing effect on the sensory nerve endings. There is also produced a marked desiccating influence which may be made use of in inflammatory conditions.

To illustrate: About twenty years ago a patient came to me with a badly swollen middle finger. This was the result of a slight wound made by a sharp instrument. The skin was hot and the pain was excruciating. The static induced current was applied by means of a pair of small sponge covered electrodes (the size of a fifty cent piece). The spark gap was extremely short and the machine was running about three hundred revolutions a minute. In five minutes the pain was gone. In ten minutes the part was soft and cool. Two years later the part was so soft that it seemed as if pus had formed. We cut into it and to our surprise found a hollow, empty space. This wound healed quickly and no further trouble developed.

D'Arsonval in 1890 conceived the idea of interposing between the outer coating of the Leyden jars a copper spiral. For charging the Leyden jars he employed a coil of large capacity. With this arrangement he made his famous experiments. Gradual improvements in apparatus have led up to our present type of transformer by means of which we are enabled to use oscillating currents of practically continuous duration in medical and surgical practice. Diathermy is the name which Nagelschmidt proposed in 1909 for this type of high frequency currents. This is now the general designation. Thermopenetration, which was the name first used by von Zeyneck, and the designation of endothermy of Delherem and Saquerriere, is now rarely employed.

These rapidly oscillating currents have placed in our hands a means of introducing electrical currents into the tissues in sufficient volume, to effect demontrable heating of the blood and of the entire body. All electrical currents possess the property of warming conductors through which they pass. Unidirectional currents cause an electrolytic dissociation, by a migratory process in the body tissues, together with a displacement of minute particles of the body's colloids; in fluids there is a wandering process of the contained salts.

The body is composed of billions of cells, each one of which is surrounded by a partially permeable membrane at which, under the action of currents of extremely high frequency and low voltage, there is a concentration which seems to have an important bearing on the development and storage of heat. The same phenomena occur during the employment of currents of low enough frequency. But as the rate of alternation increases the migration of the ions diminishes because the rapidly shifting alternation of the current impulse does not allow time enough for the resolution of molecular fixation. Instead of electrolytic dissociation, we have an extremely rapid molecular vibration which is the cause of the heat production by diathermic currents. It is probable that anabolic and katabolic changes are induced or accelerated and the oxydation processes improved. Clinical observations and the results of urinary examinations emphatically confirm this view of the matter.

The continuous and the alternating currents of low frequency can not be used in sufficient strength to produce thermometric demonstratable heating because, even in relatively small quantity, they produce painful neuromuscular and electrolytic effects. In larger quantity they produce extensive destruction of tissue and death. Mild heat imparted to the yeast cell increases its activity twenty-five per cent. and the observation of the beneficial effects of warmth on many forms of plant and animal life may lead us to assume that the introduction of warmth into the cells of the body will add to their activity, and that the diathermic heat stored up in millions upon millions of cells tends to conserve their natural resources and add to their surplus of reserve energy. After a general warming of the musculature of the body, muscular effort becomes easier, greater and more sustained effort is possible, and mental processes are also aroused to a better activity.

By means of suitable metal electrodes, we have it in our power to concentrate the diathermic heat upon any given area, we can also direct the path of the current and control its depth of penetration by proper position of the electrodes. We will observe after such a current has had sufficient time to warm a part an increase in the capillary circulation, and an increased production of sweat and sebum under and immediately around the electrodes. When heavy currents are employed this increased production of sweat is often very profuse, and it may at times be so hot as to blister the adjacent skin.

Patients find this warmth very agreeable. It is introduced from without in immediately utilizable form, without the expenditure of any of the patient's stored energy. The warming is different from that obtained by any other artificial method. It occurs from within, in the interior of the body, in which every single cell participates. Centres of heat are formed in millions of cells. This heat is only slowly dissipated. The deeper the seat of the cell, the more slowly it loses the stored-up heat. An addition of heat beyond the normal stimulates, by a reflex effect, all those functions which favor the emanation of heat. The capillaries of the skin become widely dilated, much of the blood thus drawn to the surface is taken from the splanchnic circle.

The heat passes off by the skin. This is influenced by the temperature of the surrounding air, by the amount of body covering (clothing) and by the degree of distention of the capillaries of the skin and mucous membranes. The temperature of the surface of the body is lower than that of the blood. An extensive peripheral hyperemia makes possible greater heat losses. The watery emanation from skin and mucous membranes of the air passages, the increased secretion of sweat enhances the dissipation of watery vapor. The increased rapidity of the respiratory excursions increases the activity possible by the mucous membranes. This automatic regulation of the body enables us to tolerate an addition of heat up to a definite point without changing our temperature. A strictly local application to a joint will not markedly effect the general heat capacity of the body. Large electrodes and larger currents and longer duration of the seance exercise all the powers of defense which we have detailed. Beyond a certain point a rise of the temperature of the blood of the entire body is inevitable. A relatively small amount of diathermic current, applied to a little animal like the guineapig, will raise the temperature of its body to the point where paralysis of the heat regulating apparatus of the body occurs.

The reason for this is simple. The acceleration of the blood stream at the point of contact of the electrodes is greatly intensified in a relatively short time, depending entirely on the strength and concentration of the current, and the entire volume of blood in the animal is heated to the danger point. An agent such as this which is capable of producing such widely distributed heat effects, necessarily influences the activity of the sympathetic and autonomous nervous systems.

There is no organ so deeply seated that it cannot be reached by the diathermic heat. All gland secretion can be greatly augmented by diathermy. The functions of the sweat glands, of the liver, the pancreas, the gonads, the thyroid, the kidneys, the stomach, all of the endocrines may be stimulated. By suitable application of the electrodes, proper doses and duration, we have it in our power to induce an active arterial hyperemia anywhere. The degree to which such an active arterial hyperemia may be of benefit to the patient is dependent upon the nature of the pathological condition.

It would be very unwise to apply a heavy current to an arteriosclerotic limb. The influx of an excessive quantity of arterial blood would overtax the venous system of the part greatly. The result of this would be an intensification of the pain from which the patient is suffering as well as other disagreeable consequences.

An excessive quantity of current for too long a time to a cirrhotic liver will result in an increase of accumulation of fluid in the peritoneal cavity. A safe rule to follow, if our aim be to increase functional activity of an organ or a part, is to use mild current strength of somewhat long duration.

If we wish to affect deeply seated organs like the stomach we will achieve our object more quickly with milder currents of longer duration than with heavy currents of too great concentration. The latter rouse the reflexes quickly, and a rapid afflux of blood to the part occurs which carries away a large part of the diathermic heat. In this way, the diathermic heat is hindered greatly in reaching the interior of the stomach.

It is for this reason that we frequently achieve beneficial effects with milder currents applied from different points at the outside of the body (a cross fire effect) better than with large electrodes and heavy currents.

Diathermic currents have marked analgesic properties. This analgesic effect is due to the great rapidity of the oscillations, to the desiccating influence, to the marked arterial hyperemia which it induces, and to the decongesting influence which it is capable of exerting in proper doses by relieving venous engorgement. By reason of this marked arterial hyperemia we may expect to soften scar tissue. The injection of the capillaries in scar tissue with a greater abundance of arterial blood improves the nutrition and thereby changes a lowly organized structure into one of a higher order of viability. This is evidence enough that arterial improvement in scar tissue, improvement in capillaries does take place in scar tissue and warrants us in its use. The diathermic heat has also a marked influence in retarding and destroying bacterial life in invaded structures. There appears also to be a destructive action on bacterial toxine manifested.

Indigocarmine as a Functional Permeability Test of the Liver*

By MAX EINHORN, M.D., and G. L. LAPORTE, M.D.,

New York.

Ever since the duodenal tube has given us the opportunity of a direct examination of the bile, it was natural to apply the same methods of exploration of the liver function as those applied for the kidneys. The bile being elaborated and excreted by the liver is in many respects analogous to the urine excreted by the kidneys.

Abel and Rowntree, Hurwitz and Bloomfield (1) have used tetrachlorphenolphthalein as a permeability test of the functional activity of the liver. This substance was given by the authors intravenously and the stool collected for twenty-four hours and examined with regard to the amount of phenolphthalein in the stool. In cases of liver disturbances the excretion of phenolphthalein through the bile and found in the stool was appreciably diminished.

Aaron, Beck, McNeil and Schneider (2) have improved this tetrachlorphenolphthalein method by testing the bile as it appears through the duodenal tube, by aspiration every few minutes and making the determination of phenolphthalein content in the fluid. This is certainly a great advantage over the original Abel and Rowntree method. A great drawback, however, of this method consists in the necessity of applying the tetrachlorphenolphthalein intravenously and in this way detracts from its general usefulness as a clinical method.

Indigocarmine, methylene blue and other colors have first been used experimentally on animals with biliary fistulas and later on on patients for ascertaining the permeability of the liver to these various colors.

Weil and Cecil (3), Brauer (4), and Buerker (5), were pioneers in these researches. Hatiéganu (6) was the first to apply indigocarmine in a systematic way for the testing of the liver function. He gave the indigocarmine intramuscularly and examined the bile every few minutes by duodenal aspiration. Similarly methylene blue was used by Rosenthal and Falkenhausen (7) and congo red by Lepehne (8) as a functional test for the liver. We fully agree with Hatiéganu that indigocarmine is by far the best of these dyes for our purposes, for its recognition in the bile is established much easier than other dyes.

In the present article we intend to present our experiences with indigocarmine as a convenient test for liver function. At first we tried to give this substance in suppositories by rectum or by using injections into the rectum of solutions of this substance. Both ways, however, failed utterly, as they did not appear in the bile. Then we tried the intramuscular method as suggested by Hatiéganu. Ten c. c. of a ne per cent. solution of indigocarmine proved to be ne correct amount for general use. It is selfunderstood that the injection has to be given with due septic precautions. We gave injections always in ne fasting condition of the patient, aspirated the bile efore injection and then every five minutes after the njection, and noted the first appearance of the dye the duodenal contents. We also paid attention to ne length of time that indigocarmine appeared in the ile, until its entire disappearance.

---

In cases in which there was difficulty in obtaining ne duodenal contents after the injection of indigoarmine, a few c. c. of saline solution were injected rough the duodenal tube and syphoned out. This most instances effected a flow of bile. In only rare nstances other means were resorted to in order to stablish a flow of bile. In these we usually applied instillation of twenty-five per cent. glucose soluon into the duodenum. In all these patients where ne indigocarmine test was applied, the urine was kewise watched for the appearance of this substance nd the time of excretion noted, as well as the quanty of urine containing this dye.

It appeared to us worth while to ascertain the uantity of indigocarmine excreted by the urine and r this purpose we made colorimetric solutions of digocarmine and determined the amount of this ye in the urine. We found that in cases in which nere was a relatively small amount excreted by the ver, there was a correspondingly larger quantity covered in the urine.

We have embodied the results of our work with tigocarmine as a test for liver function in Table I. On looking over this table we find that the average ne of first appearanace of the indigocarmine in ses not afflicted with liver troubles is about forty inutes. In diseases of the liver, especially when companied by jaundice, it is usually delayed, most malignant trouble of the liver, in one case not pearing until two hours after injection and in nother case of cancer of the liver not appearing at l; in one case of catarrhal jaundice the indigocarmine did not appear in the bile at all, the period of observation lasting four hours. The injection of indigocarmine also produces a stimulation of the liver secretion, resulting in the production of a dark bile, previous to or after the appearance of the indigocarmine in the bile.

In a few cases we tried the indigocarmine and also Widal's (9) *crise hémoclasique* tests. The latter test, as is well known, consists in giving the patient in the fasting condition two hundred c. c. of milk and examining the blood for the number of leucocytes every twenty to thirty minutes for a period of an hour and a half. Normally there is always an increase of leucocytes during the period of digestion. In diseases of the liver, according to Widal, there is a decrease of leucocytes instead of an increase. In Table II we present in tabular form our experiences with Widal's test in a number of liver affections and other diseases. It can be easily seen that the functional test of the liver devised by Widal does not prove of great value. We have here four cases of cancer of the liver in all of which there is a decided increase in the number of leucocytes instead of a decrease.

An Interesting Case of Laryngeal Stenosis*

By E. M. JOSEPHSON, M.D.,
New York.

I wish to place on record a case of laryngeal stenosis of a type which seems not to have been given the attention which it deserves, and regarding which practically nothing may be found in the literature.

CASE.—The patient, a laborer about fifty years of age, was admitted on May 15, 1922, with the chief complaints of hoarseness, dyspnea, and a choking sensation in the throat. The onset had been acute, eight days before admission, with chill, fever, coughing and shortness of breath. Though there had been a slight improvement in the first two days of illness, on the third day the patient's condition suddenly grew worse, and, in addition to his previous complaints, he had pain in the neck and his sputum was bloodtinged. His previous history showed that he had been under treatment for lues several years previously, but the date of the infection was not recalled; otherwise it was negative. Upon admission the patient appeared seriously ill; was dyspneic, cyanosed, and practically aphonic. His temperature was 38.5° C.; his tongue was coated and the pharyngeal mucosa, reddened and granular; stomatitis was present, the type of which was not mentioned. External examination of the neck was negative. The chest showed dullness over right lung and increased fremitus; breathing was bronchial, most markedly over the middle lobe. The heart was negative; hypertension was present. Laryngoscopic examination revealed a laryngitis. The right cord was markedly infiltrated, especially in the posterior half. On May 20th, a subsidence of the process was noted, but the infiltration in the right cord was still present. An x ray of the lung was negative. The Wassermann reaction was four plus. The examination was otherwise negative.

The patient was placed on combined treatment for a period of approximately a month, but his condition remained unchanged. On June 13th, tracheotomy was performed, in order to relieve the increased dyspnea, after which the pulmonary signs cleared up promptly. Combined treatment was then resumed. About this time laryngoscopy showed a tumor bulging and displacing the right cord, covered by a smooth, healthy mucous membrane, and obstructing the glottis practically completely. The right arytenoid cartilage was immobile. Tissue removed for biopsy was returned with a diagnosis of normal mucous membrane. A tentative diagnosis of perichondritis was made.

On August 9, 1922, I performed a laryngofissure with the object of removing the affected cartilage. The tracheotomy wound was extended and the larynx fissured from below upward. In the right half of the larynx there was found a large, dense, sharply demarcated tumor, which displaced the true and the false cords, obliterated the sinus Morgagni and filled the larynx. The mucous membrane, over the tumor, was normal in appearance. Opposite the posterior pole of the tumor, there was developed markedly a structure which has recently been described by me.

This structure consists of a sinus on the inner laryngeal wall bordered by prominent lips, located beneath the true vocal cords, and below the cricoarytenoid joint. Underlying this sinus is a group of glands, drained by a common duct opening into the sinus. In the average normal case this structure is recognizable only as a thickening of the mucous membrane at the point mentioned, in the centre of which a depression may be noted. In many normal cases this structure assumes a marked prominence (Fig. 1).

Histological sections revealed the condition shown in Fig. 2, in which we note a sinus bordered by prominent lips, into which there opens a duct (in this case about two mm. in diameter), draining a group of glands lying between the mucosa and M. vocalis. The swellings constituted by the glands form the lips of the sinus. The gland may also extend upward into the vocal cord. It differs from the racemose salivary type of gland in its compound tubular structure, and in that the gland groups are composed of mixed mucous and salivary type of elements (Fig. 3), all of which apparently drain into a common duct. It might be mentioned, in passing, that Maziarski noted many years ago the peculiar compound tubular structure of some of the glands of the larynx. Although various groupings of the secretory glands in the larynx have been described, no mention has been found of a gland group identical in position and character of composition with the one here described, and similarly drained by a common duct.

The tumor found by me at operation in our case bore macroscopically the appearance of a pathological change in the structure mentioned above. The fissured cricoid and thyroid cartilages were found to be normal. Inasmuch as the mucosa over the tumor was absolutely intact, a submucous enucleation of the tumor was undertaken. The planes of cleavage were well defined, and the tumor readily shelled out. At the bottom of the wound there lay free the arytenoid cartilage. Because it showed signs of dry gangrene, to all appearances due to cutting off the blood supply by the tumor, it was removed. The vessels were ligated, the tracheal cannula replaced and the laryngeal wound packed and drained.

---

*Read before the Laryngological Section of the Academy of Medicine, New York.

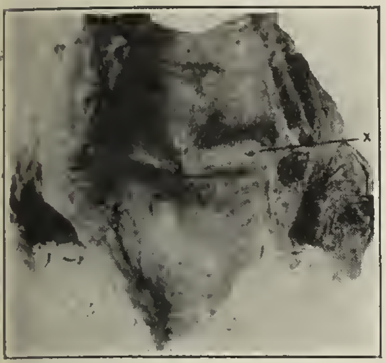

Fig. 1.—Larynx showing at (x) organ in question. (2) is a prominent well-developed laryngeal tonsil attached to the aryepiglottic fold.

The patient made an uneventful recovery, except the mild symptoms caused in the first few days after the operation by postoperative edema. When examination on October 8th revealed that the wound was completely closed, dilatation by means of the Thost bougies and Schrötter tubes was resorted to. The patient was now once again able to breathe comfortably through his larynx, which showed a fairly large and free glottic space.

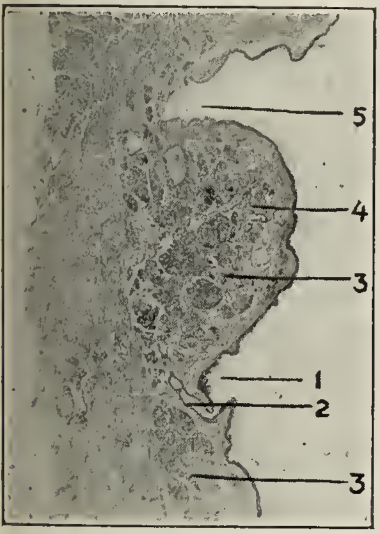

Fig. 2.—Cross-section of the structure illustrated at (x) in Fig. 1. (1) is sinus, (2) common duct draining glands (3). (4) vocal cord, (5) Sinus Morgagni.

The pathological specimens (Fig. 4) are of interest; the tumor (1) was about one and a half by one by one half sm. in size, dense and fibrous in consistency. The arytenoid cartilage (2) was grey in color and, though intact in form, showed a dry gangrene and was putrid. The dry gangrene which it had undergone was unquestionably due to the cutting off of its blood supply by the neighboring tumor; for had the process originated as a primary infection, hematogenous or otherwise, there would have been a loss in its substance.

Histological sections showed that the tumor substance consisted of scar tissue through which there were scattered areas of round cell infiltration. Giant cells or caseation were nowhere in evidence. The picture is that of a subacute or chronic inflammation healing gradually with scar formation. The nature of the inflamed structure is merely suggested by the ringlike scar bodies in the body of the tumor, but is rendered manifest by sections of the tissue at the periphery. These sections show that the scar bodies find their origin in an inflammatory process involving the glands described above, and show all stages of the process—the initial peritubular infiltration, the lysis of the gland's cells, the absorption of cell substance, and, finally, the replacement of tubules by scar tissue, which on cross section have the appearance of rings. The fibres of the M. vocalis immediately adjacent to the glands were also apparently secondarily involved. No bacteriological studies were made of this case.

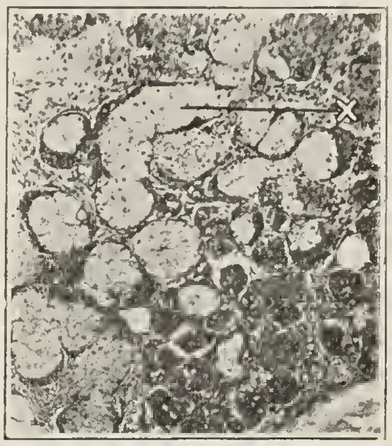

Fig. 3.—Glands (3) Fig. 2 magnified 100X. Tubular nature is seen at (x).

The question of differential diagnosis is in this case an interesting and difficult one. First, the possibility of an underlying tuberculous or luetic lesion as a basis for the condition must be considered; secondly, the question as to whether the chrondritis was primary or secondary. Acute inflammatory onset is not absolutely typical of either tuberculosis or tertiary lues. A tuberculous lesion or a gumma would have caseated and ulcerated through the mucous membrane before attaining the dimensions of the tumor. A gumma in the early stages would have rapidly responded to antiluetic treatment. The histopathological pictures rule out both possibilities; for, though there were nests of active inflammatory tissue interspersed in the scar tissue, there were no signs of tubercle or gumma formation. The matter of relative time of origin of the perichondritis seems to be settled by the fact that the perichondritis was in a stage of development earlier than that of the glandular lesion, as is evidenced by the absence of any signs of lysis of the cartilage substance, and the absence of pus about the necrotic cartilage, both pointing to a cutting off of blood supply by pressure of the tumor as the etiology of the necrosis of the arytenoid, and the glandular lesion as primary.

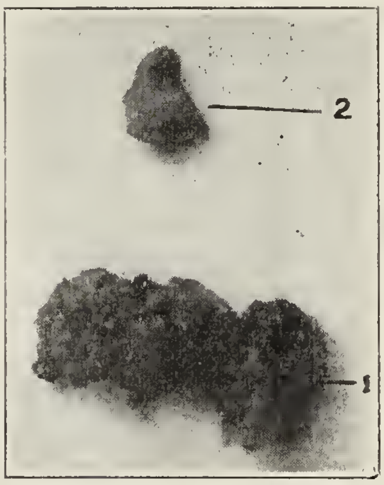

Fig. 4.—(1) Gland enucleated at operation from case here described. (2) Arytenoid cartilage, intact in form, found in a condition of dry necrosis, behind the tumor. The bulk of the tumor was so large as to cut off circulation of the cartilage.

PATHOLOGY.

The pathology of this case differentiates it from the general category of chronic submucous laryngitides, and indicates that it represents an undescribed clinical entity—a stenosis of the larynx caused by a subacute or chronic inflammation of a group of secreting glands of the larynx.

The case here presented is a laryngeal stenosis caused by a primary infection of a laryngeal structure, consisting principally of a group of secretory glands, secondarily conditioning a necrosis of the arytenoid cartilage. The onset was acute, febrile, associated with a stomatitis, and the infection initially acute, subsequently ran a chronic course. The stenosis in due time became so high grade that tracheotomy was necessary to relieve dyspnea. In view of the failure of palliative treatment, including iodides, mixed and salvarsan treatment, enucleation of the gland was necessitated. The gland was readily enucleated submucously.

Septic Portal Thrombosis

With Report of Two Cases

By WILLIAM IRVING SIROVICH, M.D.,
Superintendent People's Hospital.
and
GEORGE SCHWARTZ, M.D.,
Adjunct Surgeon, People's Hospital.
New York.

Septic portal thrombosis or pylephlebitis, although not a rare condition, is uncommon enough to warrant a brief résumé and a report of two cases.

Suppurative pylephlebitis (portal pyemia) is more common in males than in females. It is especially common in early adult life, coinciding with the age incidence of appendicitis, but it occurs at all ages, the average age in men being forty-four years and in women forty-one years (Ralston). The thrombosis may begin in the portal radicals within the liver, in the main trunk of the vein, or in the peripheral radicals anywhere within the area of the collection of the vein; and subsequently by extension the process may become widespread.

ETIOLOGY.

Usually the process begins in the peripheral radicals, being secondary to ulcerative and suppurative processes of the gastrointestinal tract. Of these the most common is ulcerative or suppurative appendicitis, more particularly in cases neglected surgically; or in which the infectious thromboses occur in the appendicular and mesenteric veins. Less commonly, ulcerative and neoplastic processes of the stomach and intestines, such as gastric and duodenal ulcer, typhoid fever, tuberculosis, amebic ulceration of the intestine, gastrointestinal carcinoma, fissures, ulcer and stricture of the rectum and anus, suppurative and gangrenous pancreatitis, suppuration of the mesenteric gland, suppurative disease of the female genitalia, and abscess of the spleen constitute the starting point of the infective thrombosis. The thrombosis occasionally begins in the main trunk of the vein, sometimes in consequence of operative trauma, but usually secondarily to a local focus of suppuration—perigastric periduodenal, subhepatic, or to gallstones in the common duct with surrounding suppuration.

PATHOLOGY.

The process may be more or less localized or quite widespread. The vein is enlarged, swollen, softened, congested, edematous, and is filled with a more or less necrotic purulent or sanguineous purulent material partially or completely obstructing the lumen. Not infrequently there is obvious purulent infiltration of the wall of the vein, (perivascular lymph spaces) and in the adjacent connective tissue, usually on the right side. When not entirely liquefied, the clot is more or less friable, occasionally free in the lumen, but usually it is more or less intimately attached to the intima. The liver is usually enlarged and contains foci of necrosis, or multiple abscesses; the spleen is enlarged and softened, not infrequently there is localized or generalized purulent peritonitis; there may be a purulent pleuritis, and sometimes secondary abscesses develop in different parts of the body.

SYMPTOMS.

Since suppurative pylephlebitis is a secondary disorder, the symptoms directly attributable to it are preceded by those of the disease to which it owes its origin, notably, appendicitis and cholelithiases. The onset of the pylephlebitis is usually sudden, and is manifested by the phenomena of septicopyemia—irregular chills, fever, and sweats, a soft, compressible rapid pulse, leucocytosis, and general prostration. To these may be added extension of the abdominal pain beyond the seat of the original disease, enlargement and tenderness of the liver, which occur in about fifty per cent of the cases, and enlargement of the spleen, which occurs in twenty-five per cent. of the cases. Vomiting occurs in forty per cent. of the cases (Rolleston). Diarrhea occurs in thirty-two per cent. and hematemesis in eighteen per cent. of the cases. Langdon Brown says that in sixty per cent. of the cases the onset is acute, that is, although the thrombosis may be a gradual process, symptoms due to complete obstruction develop suddenly. The most marked of these symptoms consist of ascites, enlargement of the spleen, and various disorders of the gastrointestinal tract. Rolleston says that ascites is present in sixty-five per cent. of the cases. Symptoms referable to various complications, such as pleurisy and brain abscess, may supervene.

DIAGNOSIS.

This rests upon an obvious primary cause, the development of a septicopyemic state, and evidences of the involvement of the liver, with perhaps slight jaundice. Differential diagnosis between Charcot's intermittent hepatic fever, other forms of liver abscess, other forms of septicopyemia, typhoid fever, and the chills and fever may simulate malaria.

PROGNOSIS.

The disease is fatal in a great majority of these cases, especially when the main trunk of the vein is involved, or when there are multiple abscesses in the liver. However, cases of recovery have been reported.

TREATMENT.

Pylephlebitis is more easily prevented than cured. Appendicitis and other etiological factors should be treated early, so as to prevent the formation of an infectious emboli. When developed the treatment of pylephlebitis is the same as a liver abscess. Ligation of the portal vein has been reported without avail.

CASE REPORTS.

CASE I.—Male adult, forty-three years of age, married, a truck driver, complained of pain in the right upper quadrant, with nausea and vomiting, jaundice, chills and fever, and ascites. His family history was practically negative with regard to the present condition. At the age of eighteen he had had typhoid fever, with no complications. He had had lobar pneumonia at the age of twenty-four and again at thirty-two. His present illness began seven days before admission, when he was seized with generalized pain in the epigastric and right hyperchondriac region. He vomited bile for two days, the pain finally becoming localized in the epigastric region, when the vomiting ceased. The following morning he had a chill, which lasted a half hour, followed by high temperature and later by profuse sweats. He noticed at this time a rapid enlargement of the abdomen, and he also became slightly jaundiced. The chills, fever, and sweats occurred the following day and the ascites and jaundice became more marked. He passed a small quantity of blood by rectum. He was taken to Bellevue Hospital, but the following morning was sent home to be treated by his family doctor. Because of the marked ascites the family physician introduced a trocar to relieve it. The following morning the patient was brought to the People's Hospital.

Physical examination showed an adult male who appeared acutely ill, with peritonitic facies, marked jaundice of the entire body, rapid and shallow respirations, and crying aloud with pain. The head was negative. The eyes showed pupils irregular, dilated, and reacted to accommodation but not to light. Extraocular movements were all right. Sclera and conjunctiva show marked icteroid tinge. The nose, mouth and ears were negative; also the chest and lungs. The pulse rate was 140 regular, and the heart sounds were fair; no murmurs. The abdomen was markedly distended. In the left lower quadrant a puncture wound, where the trocar had been inserted, was somewhat inflamed. There was exquisite tenderness in the epigastric and right hyperchondriac regions and marked rigidity of the entire upper abdomen. Fluid could be elicited with shifting dullness and a fluid wave. The liver reached three fingers below the costal margin; the spleen was not enlarged; the kidneys could not be felt, and Murphy's sign was negative. Rectal examination revealed nothing.

Laboratory findings: Temperature, 103°, pulse 140, respirations 28. Blood count; white blood cells, 28,600; polymorphonuclears, 89 per cent.; lymphocytes, 11 per cent. No malarial parasites were found. The urine showed a slight trace of albumin, but was otherwise negative. The stools showed no blood, although the patient said he had passed blood. Blood culture was negative. Blood pressure, 140/60. Wassermann, four plus.

In the hospital the patient continued to have chills and a temperature which went as high of 106°, with profuse sweats. The following morning he showed signs of a generalized peritonitis and passed away the same day.

Autopsy findings: Permission for autopsy was granted for abdominal examination only. The abdomen was found to be full of a serofibrinous fluid, with evidences of a generalized peritonitis probably caused by the introduction of infection with the trocar, as the line of entrance was markedly inflamed. In the gastrocolic omentum there was a large abscess cavity about the size of an orange. It was well incapsulated. The abscess cavity, as far as could be ascertained, had no connection with the transverse colon or stomach, but because of the close proxmity of the stomach to the abscess cavity, there was little doubt that the abscess was the result of a perforation of the stomach. The liver was large, swollen, red and congested. The liver was removed, and the portal vein was found to be occluded completely by a large septic thrombus. Frank pus was found in the portal vein and the liver on section showed miliary abscesses. The gallbladder, appendix, and rectum were negative, as was also the remainder of the gastrointestinal tract.

CASE II.—Female, aged thirty-eight, married. Her chief complaint was pain in right upper quadrant, nausea, vomiting, jaundice, chills and fever. Her family history was negative, and her past history was also negative, except that she had had recurrent attacks of gallstone colic in the last seven years. Her present illness began six days before admission, when she had had an attack of gallstone colic, for which she was given morphine as usual and the pain subsided. The following day she noticed that she was getting slightly jaundiced, and that evening she had a chill, followed by high fever and perspiration. On admission to the hospital, her temperature was 97°, pulse 130, respirations 24. That evening she had a chill and the temperature went up to 107°, with pulse 140, and the jaundice gradually increased.

Physical examination showed a patient who looked acutely ill, but apparently free from pain. Head, eyes, ears, nose, etc., were negative; chest, heart and lungs were normal. In the abdomen there was marked sensitiveness over the gallbladder with slight rigidity of the right upper quadrant. There was a marked yellowish color to the skin. The abdomen was flat. The liver could be felt at the costal margin. The spleen and kidneys were not palpable. No fluid could be elicited. Rectal and vaginal examinations were negative. The patient continued to have a chill every day with the temperature going as high as 107° and 108°, and increased jaundice.

Laboratory findings showed the blood pressure to be 120/70. The blood count was white blood cells, 4,600; polymorphonuclears, 88 per cent.; lymphocytes, 12 per cent. No malarial parasite was found. The urine was entirely negative.

The diagnosis rested between portal thrombosis and Charcot's hepatic fever from a stone at the ampulla of Vater, and operation was decided upon. The gallbladder was found to be full of stones and was removed. There was a stone in the common duct which was removed and the duct drained. The appendix was normal. After the operation the patient continued to have chills daily with high temperature and marked prostration. The blood count now was 22,000 white cells and 92 per cent polymorphonuclears. The patient continued to grow worse and died four days after operation.

Autopsy findings: The liver was removed through the old incisions and presented the following findings. The portal vein contained a large septic thrombus which included about three quarters of the lumen of the vein. The liver showed miliary abscesses.

CONCLUSIONS.

1. Pylephlebitis is secondary to disease of the gallbladder, appendix, or remainder of the gastrointestinal tract.

2. The condition is invariably fatal.

3. The symptoms are classical and there is little difficulty in making a diagnosis.

203 Second Avenue.

Further Observations on Intussusception in Infants

By L. MILLER KAHN, M.D., F.A.C.S.,
New York,
Attending Surgeon, Beth David Hospital, and Associate Surgeon to the Lebanon Hospital.

In presenting this brief paper on acute intussusception in infants, it is with the knowledge that much has been written on the subject; that in the main the disease has been fully described, and that the chief manifestations of the condition make its recognition easy to the careful clinician. I believe that no apology is necessary, however, in view of the fact that intussusception is a much commoner disease than is generally supposed, that there has been discovered something more of its pathology and mechanics, and that there is still room for improvement in the early recognition of intussusception and the submission of the patient to operation at an earlier period after the onset of symptoms.

It has been shown repeatedly that the mortality in children suffering from intussusception is in exact ratio to the number of hours elapsing between the onset of the symptoms and the time of operation and that the deaths in this condition are due almost solely to the degree of advancement of the pathological condition.

What actually happens, anatomically, in point of time, is this: One loop of bowel is swallowed by another and along with the swallowed loop there is taken in a certain amount of its mesentery and a mass is thereby formed. In this process the mesentery is kinked, its venous circulation is disturbed, the ingested loop is squeezed and it oozes blood and mucus; its lumen is constricted and with increasing edema becomes closed entirely. After a few hours the now congested and edematous loop loses its vitality through the strangulation of its arterial circulation and this intussuscepted section of the bowel dies.

And in point of time there is a perfect synchronism between the symptoms of the disease and the anatomical pathology. With the ingestion of the loop of bowel and the dragging on its mesentery there is the consequent abdominal shock, manifested by pallor; the pain and the reflex vomiting are due in large measure to the traction on the mesentery. Then comes the intermittent spasm as the bowel attempts, by powerful contraction, to rid itself of the obstruction. With the venous stasis in the intussuscepted loop comes the blood and mucus in the stool and in a longer or shorter period, depending on the severity of the condition, the closure of the bowel and the failure to pass stool or gas. For our purpose it is unnecessary to follow the picture to gangrene. As there is almost perfect agreement between the condition present and the symptoms manifested, it must be said at once that the degree of the pathological states and the degree of the symptoms are subject to wide variation.

In the main there are four types of intussusception that occur most commonly:

1. The ileocolic, in which a portion of the ileum is invaginated into the colon but the ileocecal valve remains fixed.

2. The ileocecal, in which the ileocecal valve acts as the starting point of the intussusception.

3. The enteric or ileoileal, in which one loop of small intestine is invaginated into another.

4. The colocolic, in which some portion of the colon is invaginated into a neighboring portion of the large bowel.

This classification is here repeated because it is necessary to the probable explanation of the cause of the disease. Of the previous explanations of the etiology none have been entirely satisfactory, and it remained for Perrin and Lindsey, basing their conclusions on the work of Walton, Fitzwilliams and D'Arcy Power, to advance what seems upon careful consideration a workable solution.

As something like seventy-five per cent. of all intussusceptions in infants occur between the fifth and ninth month, and approximately eighty-five per cent. of these are of the ileocolic and ileocecal types combined, any explanation of the etiology of the disease must take these two factors largely into account. D'Arcy Power has pointed out the fact that in infants the colon is little larger in diameter than the ileum and that the disproportion between the two in later life is the result of postnatal development. An examination of the ileocecal valve in the infant shows that it projects about half an inch into the colon, thus constituting a natural intussusception of the ileum into the colon. "In a child of three months the terminal inch of the mucosa of the ileum is studded with masses of lymphoid tissue which form a complete ring about the lumen of the gut; the aggregation of lymphoid tissue becomes less and less marked as the ileum is examined farther away from the valve until, at a point six inches above the valve, except for isolated Peyer's patches, there is no special aggregation to be found."

"At one year it is seen that the ileocecal valve is still prominent, but the patches of lymphoid tissue at the termination of the ileum, though well marked, is less developed." Thus it is shown that during the first year of life the lymphoid tissue in the ileocecal valve and the degree of projection of the valve into the cecum are at the maximum. Both are much less marked during the second year of life and the prominence of each gradually decreases as adult life is attained.

From the fifth to the ninth month of infancy additional articles of diet are given children, the intestinal digestion is disturbed, there is a swelling of the lymphoid tissue sufficient to permit this swollen mass to act as a foreign body, and in the attempt of the bowel to rid itself of this, the foreign mass is forced onward and is in turn swallowed by the next succeeding loop.

It is a common observation that intussusception occurs mainly in well nourished children and it is in precisely these cases that the lymphoid tissue is best developed. Most of the problems confronting us are hereby answered, the presence of the excessive lymphoid tissue occurring at the time and in the region of the greatest frequency of the disease. It might be added that isolated areas of lymphoid tissue in the colon and in the small bowel readily account for the occasional colocolic and enteric intussusception. Contrary to what might be suspected in enterocolitis the lymphoid tissue is atrophied and it is the general experience that intussusception is not prevalent in seasonal enterocolitis. The greater frequency of intussusception in male children still remains to be explained and it may be that the fact that "male babies are age for age larger and heavier than females and the lymphoid tissue of the gut varies directly with the size of the child" gives us the necessary clue.

This completes our clinical picture. A well nourished child, usually under two years of age, generally in our own cases breast fed, is seized with cramps, turns pale, vomits, perhaps has one or two stools without blood, and then passes blood and mucus by rectum, either with or without stool; perhaps a mass is felt by abdominal palpation and much less likely the examining finger in the rectum may feel the intussuscepted loop of bowel. But the classical case is rare, and waiting for the case to become classical may result in the patient's death. The history of intermittent attacks of screaming with evidence of severe pain, the vomiting, and the blood and mucus passed by rectum, with failure to pass stool and gas, should be sufficient to establish a diagnosis. In about fifty per cent. of the cases that I have seen an abdominal mass could be palpated; in the remaining fifty per cent. no mass was palpable, but its presence was proved by operation.

In a small percentage of the cases coming under observation, with typical histories of intussusception, the patients had apparently recovered and the intussusception been reduced at the time I saw them a few hours after the onset. Under continued observation no further symptoms developed. On the reduction of the intussusception the child's color returns, there is passage of a normal stool, the crying abates, and repeated feedings are retained. This phase of the question is of the utmost importance, as it is well known that children suffering from intussusception have periods of quiescence lasting several hours, and the distinction between this quiescent period in a child actually suffering from intussusception and one in whom the intussusception is relieved must be made with great clearness.

And now in contradistinction to what has been said, permit me to recall that the intussuscepted bowel need not necessarily be completely occluded, and that while the history of the case may be typical, the symptoms may vary widely in degree. In these cases the invaginated bowel may be only slightly constricted and congested, and may function for some days in spite of its altered position. The condition then becomes subacute and particular caution is necessary in order that the symptoms may not be overlooked or regarded too lightly.

As to the treatment it need scarcely be said that operation at the earliest possible moment offers the best chance of recovery. In cases diagnosticated within the first twenty-four hours, and operation performed promptly, there will be almost 100 per cent. of recovery. After the first twenty-four hours, as has been said, the mortality is that of the disease.

In a previous paper I reported all cases of intussusception admitted to Lebanon Hospital over a period of years. The number at that time was forty-six. I now wish to add twenty-five additional cases, of which six patients died, giving a mortality rate in the last series of approximately twenty-five per cent. Of these six patients not one was operated upon within eighteen hours of the onset of the symptoms. The time elapsed varied from twenty hours in one instance up to seventy-two hours in two of the cases.

Since July 1, 1922, I have seen seven patients in whom the diagnosis of probable intussuseption had been made. In four, operation was done, the intussusception found, and the invagination reduced. In two of the cases the history of intussusception was clear, but a careful analysis of the symptoms as they presented at the time I saw them, as related above, led me to believe that the intususception had been relieved. No operation was done in these. The seventh patient showed blood in the stool but a typical history of the condition was absent and examination of the point of the syringe used in giving the baby an enema, satisfied me that there had been some trauma. No operation. All of these seven patients recovered. In this series all of the patients were seen early in the disease, and when operation was indicated, this was done promptly. I have separated this year's cases in order to show that there has been a distinct improvement in the early diagnosis of this condition by the physicians.

The total number of the cases of intussusception occurring in this city is large, as evidenced by this report of seventy-one cases within a few years admitted to Lebanon Hospital. The number of cases occurring in an individual practice is generally small and that fact often accounts for the delay in diagnosis and treatment, as owing to its relative infrequency the diagnosis does not suggest itself.

Cancer of the Breast

*What Can the General Practitioner Do to Improve the Prognosis?**

By LEO B. MEYER, M.D., F.A.C.S.,
New York.

Eighty-six thousand deaths from cancer last year, eight thousand of which were due to cancer of the breast! Surely a mortality such as this should make us all keen to do everything possible to diminish it. The Society for the Prevention and Control of Cancer, as its share toward this end, holds meetings, mostly among the laity, at which the subject is discussed in a nontechnical way. This campaign of education, it is hoped, will result in patients consulting their physicians before extensive damage has been done, possibly before a positive diagnosis of cancer can be made. Much has been done but much still remains to be done. Patients do consult their physicians earlier than formerly for abnormalities of the breast; this is statistically proved in the practice of many surgeons by the greater proportion of nonmalignant growths removed today compared with former years. According to Bloodgood, more than half the breast tumors seen by him today are benign. I am sorry to say that this is not true in my practice. Over seventy-five per cent. of the breast tumors seen by me are malignant, the redeeming feature being that today I see many more in an early stage than was formerly the case. Women should know that breast tumors are often benign; this knowledge would relieve them of the fear that the discovery of a breast tumor dooms them, but they must learn that they cannot be the judges of the character of a growth. Immediate consultation with a physician is the price they must pay for their protection.

Some day, not far distant I hope, women will have learned that breast tumor means surgery just as acute appendicitis does. Their education will have advanced so far that they will know (what today every physician should know and explain to his patients) that only in this way can the development of cancer in the growth be forestalled, or if upon examination of the specimen the growth should prove to be malignant, the subsequent radical treatment in this early stage will increase the probability of permanent cure, in fact make of the probability almost a certainty.

At this stage, it seems to me, a little introspection might not be amiss. Are we quite sure that the patient with a precancerous lesion always gets the best advice when he consults us? What has become of that patient who consulted us a year or more ago with a small movable growth in the upper outer quadrant of the breast, almost in the anterior axillary fold, who was told that the condition amounted to nothing at all, nothing but a small gland or possibly a cyst or a little fibroma, and was advised to go home and forget about it? Possibly we gave her a placebo of some ointment or some potassium iodide internally, and salved our conscience by telling her to return if the growth ever bothered her; or, possibly, we did a little better and kept the patient under observation to see whether the growth would disappear under our treatment or show signs of changing its character. Did that patient remain well or did the growth change its character either under our observation or under the observation of the patient herself? If the character of the growth changed, the patient's chances of cure were certainly diminished by the delay; even if it did not change the advice was poor, for all of us, even the most skillful in diagnosis, must acknowledge that rarely can we be certain that malignancy has not started in an apparently innocent growth, and never can we be certain that the growth will not at some future date become malignant. This being so, how is it possible for us to refuse to advise our patients along the lines suggested by those who have had the greatest experience in dealing with breast tumors. Such advice should be that all breast tumors that are not frankly malignant are potentially so, and if occurring in a woman over twenty-five should be surgically treated.

I have said that the cancer propaganda has seemed to do much towards influencing women to consult their physicians earlier than formerly for trouble occurring in their breasts. This was very forcibly impressed upon me during the past year, when in the course of one week three patients were referred to me with a diagnosis of probable carcinoma of the breast. All of the women were positive that the growth was less than a week old (one had noticed it only the day before). This certainly was an encouraging state of affairs—women who consulted their family physicians immediately upon noticing something wrong with their breast instead of procrastinating for fear that they might be told a disagreeable truth, physicians who referred their patients to a surgeon promptly instead of placating them, or fooling themselves by the use of various medicaments internally and externally, or by simply watching the growth to see if it remained stationary or increased in size, or possibly waiting until a positive diagnosis could be made, although I am happy to say that this does not occur very frequently today. I said this was encouraging—and it was. But frankly there is another picture. Less than a month after this, a patient was referred by her physician who had previously telephoned to me that he was sending a patient with a growth in her breast that he had been watching for six months; he felt that the growth should come out to avoid future (?) trouble, though he did not consider it malignant then. He said he thought that it would be advisable to examine a frozen section of the growth at the operating table to guard against a possible malignancy.

Upon examining the patient (a woman of fifty) I found a large hard growth in the upper outer quadrant of the breast, a growth adherent to the skin and deeper parts with enlarged axillary glands adherent to the skin; in other words, a condition in which the prospect of cure, even by a radical operation, was none too good, because of inexcusable procrastination. I performed a radical operation without first removing a specimen for examination, explaining to the patient's physician as diplomatically as I knew how that the case was so definitely one of malignancy that the removal of a specimen for microscopical examination before performing a radical operation was going to needless trouble, delay and expense, and furthermore was exposing the patient to the added risk (slight though it might be) of spreading the malignancy by cutting into it. My feeling on the subject of frozen sections of breast tumors (examined at the time of operation) is that they should be employed only in the event that the surgeon considers the growth benign or is very doubtful as to its malignancy. If a surgeon of experience makes a preoperative diagnosis of cancer of the breast, the patient is better off to have the breast operated upon radically without running the chances always associated with the examination of frozen sections. I know that many surgeons believe otherwise, and have all growths (except those that could be diagnosed as malignant on sight by anyone) submitted to at least gross examination before performing a radical operation, and if this examination is not decisive they rely on the examination of a frozen section. Personally, at the present time I believe more good will be accomplished by the average surgeon, who after all operates upon the majority of patients, if he does a radical operation upon all cases in which his clinical diagnosis is that of cancer, and if he makes use of the frozen section only in those cases in which his probable diagnosis is nonmalignant growth.

---

*Read before the Harlem Medical Association, January 3, 1923.

In spite of my diplomacy in the case just referred to, the physician was evidently so offended at my not following his suggestion that from that day to this he has failed to send another patient to me, though previously I had been favored quite often, and this in spite of the fact that the examination of the removed specimen showed carcinoma.

We are, therefore, confronted with the fact that although today many more women than formerly consult their physicians as soon as they notice anything abnormal in the breast, there are many who put off their first visit so long that real help is impossible. To overcome this tendency to delay is the object of the cancer propaganda work that is being so efficiently carried on; it behooves each and every one of us to let no opportunity pass to help this work along. Much can be done to help if we make careful, painstaking examinations with this end in view, whenever patients present themselves for examination for any condition whatsoever, even a minor one. There is no reason why a woman (or for that matter a man) undergoing a chest or abdominal examination, should not be looked over carefully for a possible precancerous lesion.

Last spring a man with cancer of the breast was sent to me by his physician, to whom he had been referred by an examiner of one of the large insurance companies who had made the usual routine examination offered to the man as a policy holder of the company. That was good work on the part of the examiner, as the lesion was a small one near the areola and could have been overlooked very easily or passed over as an unimportant skin condition. There is no reason why a family physician, one who takes an interest in his patient, should not make it his business to do the same thing. We are constantly complaining that our preserves are being poached upon, but the success of the poacher is often due to the fact that we don't keep our eyes open.

However, this propaganda does not reach that medical man who when he sees a breast tumor either does not grasp the possibility of service to his patient, or who believes that he is able by "watchful waiting" to recognize the moment a tumor becomes malignant and requires operation. That man has not yet learned that the best prognosis is for those patients whose tumor has been removed before the malignancy starts.

At this point I wish to record my objection to the treatment by radium or x ray of a patient suffering from cancer of the breast, unless the patient is referred by the surgeon himself, or by the family physician after consultation with the surgeon. Among 885 malignant breast tumors reported by Bloodgood, four per cent. of the patients were under the age of thirty when the lump was first observed. In some the tumor had been in existence many years before malignancy started; in fact, its very existence for many years meant that the original growth must have been benign. Knowing, therefore, that so many malignant growths were at one time benign, and that their removal in the benign or precancerous stage forestalls the development of so serious a malady, why is it so difficult to be able to induce all physicians to advise or consent to the removal of the growth as soon as discovered?

Twenty or twenty-five years ago there might have been some excuse for this attitude. Many surgeons believed that their tactile sense was sufficiently developed to enable them to distinguish with considerable certainty between a benign and a malignant growth; but today they are not quite so sure of their skill, for all have diagnosed as benign, cases that later proved to be malignant. This is especially true in women over twenty-five. Under twenty-five years of age everyone can take a chance, unless the growth is frankly malignant. I personally never saw a cancer of the breast in a woman under twenty-five years of age; Bloodgood reports one in a woman of twenty-one.

With human nature as it is, usually shrinking from looking bad news in the face, it is well to have in mind some plan of action when confronted with conditions such as this. Today the consensus of surgical opinion as to the best plan of action to be followed when dealing with breast tumor is:

First: A freely movable, nonadherent breast tumor, which has the feel of a cyst, or fibroma or adenoma, in a girl or woman under twenty-five, need not be removed so long (and only so long) as it does not increase in size or give annoyance in other ways, such as causing pain. Bloodgood prefers to make the age limit twenty, and advises the removal of the growth even between the ages of twenty and twenty-five, which period he considers a doubtful one. Any growth which has not disappeared by the time a woman has reached the age of twenty-five, or which makes its first appearance then or later, should be removed even if the surgeon considers it benign, because one never knows when malignant degeneration may begin; a tumor which is benign and innocent today may begin its malignant change tomorrow, or it may have in its centre a small quiescent cancer deposit, which may start growing rapidly at any moment; so why wait? The only way that we can improve our results (now that our operation is fairly standardized) is to operate early, preferably in the precancerous stage, or if cancer is present, before a positive diagnosis can be easily made. Nothing can be gained by waiting. The operation at this stage is simple, can often be done under local anesthesia, and usually with but slight scarring or without visible scarring if a Warren operation is done. When the axillary glands are once involved the percentage of patients living beyond the five year period is very small (about twenty per cent.) (1).

From the viewpoint of diagnosis: If the first symptom noticed is pain in the breast, and this is followed by a growth, or if pain is the only symptom (which is often the case), the condition is rarely malignant. However, as there are cases in which a breast tumor preceded by pain is malignant, one must never permit this sequence of symptoms to enter into a decision for or against operation, though one may permit it to influence our preoperative prognosis. The safest way (the only way which will cause no regrets) is to remove all growths occurring in women over twenty-five.

A word now on the significance of bleeding from the nipple. A bleeding nipple of itself does not indicate cancer; many such have been present for years without operation, the patient remaining in perfect health. This is one occasion where watching is permissible; however, careful watching is necessary, for the appearance of a growth changes the aspect. Bleeding from the nipple plus growth means operation, either removal of the growth alone, or a radical operation for cancer, depending upon the judgment of the surgeon himself before operation, or the judgment of the surgeon and pathologist during operation, such judgment being formed by a careful examination of the gross appearance of a cross section of the removed growth, or if necessary by an examination of a frozen section made at the time.

Retraction of the nipple means cancer, even without tumor, unless there is evidence of an old mastitis or unless the retraction has been present for a long time. Even if considered nonmalignant, it must be watched carefully and constantly. I do not believe that any physician without wide experience in the diagnosis of breast conditions should on his own responsibility decide that a retracted nipple in a particular case is not malignant.

I have purposely omitted detailed discussion of the differential diagnosis of the various breast tumors, for the real object of this paper is to bring home the importance of operative procedure of some sort on every tumor of the breast occurring after the age of twenty-five. In the light of present day knowledge of the possibility of the presence of cancer, in even apparently benign growths, and the frequency of the development of cancer in growths many years after their presence becomes known to patients, any other course than this should not be taken into consideration. Simple removal may be all that is necessary, but careful microscopic examination of all (even the most evidently benign) growths should be made, and any further operative procedure should depend upon what is found.

To return to the subtitle of my paper—What can the general practitioner do to improve the prognosis of cancer of the breast? 1. He can educate himself to examine for breast tumor every woman whose chest he is called upon to examine for whatever reason. 2. He can learn to know and believe that breast tumor (i. e., a single tumor in one breast) means operation. 3. He can do his utmost to educate his patients to recognize the importance of any abnormality whatsoever in the breast.

DISCUSSION.

Dr. Joseph Colt Bloodgood, of Baltimore: A discussion of breast tumors is always timely. With Dr. Meyer's views as to the general handling of these cases I am in complete accord, for I believe that all solitary growths in the breast should be treated surgically. However, attention should be called to the fact that as a result of the educational campaign women are coming under observation for conditions of the breast for which operation is not indicated, such as pain, painful scar, discharge from the nipple, indefinite single or multiple tumors, a few definite multiple tumors, hypertrophy of the breast, etc.

I wish to emphasize the importance of palpation. If a single definite tumor is to be felt in one breast and the patient is over twenty, operation is indicated. The essential feature is, Is there a definite tumor? Many of the cases we see today are multiple indefinite tumors involving usually both breasts—the shotty mastitis; the edge of the breast is distinct and feels like a saucer. In the past the majority of these cases have been treated as cancer. This is the safer procedure until one has learned to recognize the condition as a benign lesion. Another condition which is benign but which it is safer to treat as cancer until one has learned that it is benign, is the wormlike tumor found under the nipple, usually bilateral, and due to dilated ducts. When inflamed the skin becomes reddened and the nipple may be retracted, the condition assuming the clinical picture of malignancy. It is safer to treat these cases as cancer.

The most common type of benign lesion for which operation is not indicated, is the lumpy breast, due to multiple indefinite tumors. If there are definite tumors in both breasts, or several definite tumors in one breast, the chances are that the condition is benign; it is safer, however, to explore at least one tumor to ascertain its pathology. If benign, remove it; if an adenoma, remove all the tumors; if a blue domed cyst or a lipoma, remove only the largest tumor; if malignant, do the complete operation for cancer.

As to the method of examination: I go into the history after I have examined the patient, permitting no suggestion as to which breast is involved. The patient should be stripped to the waist, reclining with hands clasped above the head. Inspect both breasts carefully. Note any change in color of skin, condition of nipple, evidence of discharge from nipple, whether one breast is larger than the other. A visible small tumor suggests malignancy. Palpate both breasts with both hands, then each breast with both hands. In the majority of cases a definite tumor is never overlooked, but schirrous carcinoma may be smaller than a ten cent piece.

In some instances palpation alone suggests cancer. The growth is hard, irregular, nodular; in other words, clinically malignant. It must be remembered, however, that a benign tumor may feel like cancer, and a malignant tumor may be smooth and lobular, suggestive of benignancy. If the tumor is clinically malignant it is safer to perform the complete operation for cancer without exploratory incision. There is no question that a small percentage of complete operations will be done for benign tumor, but it is safer.

SUMMARY.

There are: 1. Benign lesions, such as lumpy breast, multiple tumors, discharge from nipple without tumor, painful breasts without tumor, etc., for which operation is not indicated. 2. Clinically malignant lesions in which it is safer to do the complete operation for cancer without exploration. 3. Clinically a definite tumor with no definite sign of malignancy. This tumor must be explored and the patient should be prepared for the radical operation if the exploration indicates malignancy. When in doubt do the complete operation. I receive specimens from all over the country, and for the last five years it is a very rare occurrence to receive a malignant tumor in the laboratory for which an incomplete operation has been performed. This is a mistake which should not be made. Quite frequently I receive benign tumors for which the complete operation for cancer has been performed. This is the mistake which must and should be made.

Dr. Howard Lilienthal, of New York: I congratulate you upon the rare opportunity of hearing and discussing such an important topic as cancer of the breast presented in such a masterly manner by Dr. Meyer and Dr. Bloodgood. I think that in certain instances the classical radical operation in cancer of the breast should not be advised. I refer to the enormous neglected ulcerating tumors, particularly in elderly people, in which growth has been slow and axillary involvement is not demonstrable. In these cases, especially when the patients are poor operative risks, it is safer and more truly conservative to remove the breast gland alone, and treat the axillary region postoperatively by radiation; and while we are on the subject of x ray therapy I will state that for the last three years I have made it a practice to send every patient with a breast cancer for preoperative x ray therapy, postponing the operation for two weeks so that the extent of any possible erythema may be known. Finzi, of St. Bartholomew's Hospital, London, believes in this method, and Ledoux-Lebard, of Paris, has also emphasized this point. The preliminary radiation may or may not reduce the size of the tumor, but it will in any event minimize the danger of metastasis from tumor tissue possibly liberated at operation.

There is only one point in which I am inclined to differ from Dr. Meyer. Dr. Meyer thinks that nonmalignant tumors should be removed for the reason that they may become cancerous. In talking this matter over with Dr. Francis Carter Wood, he stated that benign tumors do not become cancerous, that a cancer may develop in a benign tumor the same as it may develop in any part of the body, but that it is not a transformation of benignity into malignancy. It is my opinion that neoplasms of the breast should be removed because they may be cancerous, not because they may become cancerous. The therapy is the same as that advocated by Dr. Meyer but the reasoning is different.

Dr. Benjamin T. Tilton, of New York: In his discussion of Dr. Meyer's paper Dr. Bloodgood referred to the importance of the physician being familiar with the changes in consistency of the breast during pregnancy and lactation. I should like to call attention to the great importance of discovering a carcinoma before delivery as lactation results in a very rapid growth of the tumor and dissemination through the lymphatics. Operation should always be performed before delivery even though the patient is in the last weeks of pregnancy. Operation deferred until lactation means usually death from metastasis in a few months. All cases in which I have operated after having the patient brought to me shortly after delivery have terminated fatally with extraordinary rapid dissemination. On the other hand, I have operated in a number of cases during the last months of pregnancy and no recurrence has occurred. In one case delivery occurred on the tenth day postoperative without untoward incident. It is of course very important to these women in the later months of pregnancy to be sure of the diagnosis before subjecting them to the radical operation. Excision of the whole tumor and immediate frozen section report from the laboratory should be employed in doubtful cases. In general, it is regrettable that many physicians delay in sending cases to the surgeon because the swelling in the breast does not have what they think are the typical signs of carcinoma. It is, for example, not painful, is not situated in the usual position, the pig skin appearance is not present, etc. The important thing is the presence of an abnormal lump in the breast, especially after twenty-five. This lump should not be kept under observation, but the responsibility shared at once with a competent surgeon who will remove it either by excision or radical operation unless he is positive in his own mind after long experience that it is a benign nonoperative affair, such as chronic mastitis.

Dr. A. O. Wilensky, of New York: The keynote of the discussion has been education. It is not sufficient to educate the laity. Physicians themselves are in need of much more knowledge in regard to malignant tumors than they possess now. A great deal of emphasis has been laid on the presence of a palpable mass. Permit me to make comparison with appendicitis. A cancerous growth in the stage in which it presents a palpable mass is analogous to an appendicitis which has been allowed to go on to the stage in which an abscess has formed and localized. All will surely agree that such an appendicitis has been allowed to go on just a little too long. We should have preferred to get the disease in the earliest stages—in the socalled catarrhal stage. So with the tumor; a mass is exactly equivalent to an abscess and already we are somewhat late in our therapeutic attack on the neoplastic disease. In order to obtain the best results with operation on malignant breast tumors we ought to be able to recognize the disease before a palpable mass is present. To carry the analogy still further, a breast carcinoma with a palpable tumor and enlarged tumor bearing glands in the axilla, above the clavicle or in the mediastinum, is a very late condition; it corresponds to an appendicitis with a localized abscess and with general peritonitis of a severe grade. All of us know that when appendicitis has gone so long as to produce peritonitis, someone has blundered, either patient or doctor, let us say in charitable spirit, unknowingly. And so with the tumor; the presence of infected glands means that the disease is in its late, perhaps terminal, stage.

So we see that we doctors are ourselves in need of much more knowledge concerning the very earliest stage of neoplastic disease. Much has been said of precancerous conditions. In the breast this refers to those degenerative forms of pathology called chronic cystic mastitis, a condition characterized by a profusion of irregularly dilated acini with change in the interstitial tissue and frequently with hyperplasia of the glandular epithelial elements. Sometimes this latter hyperplasia becomes lawless and uncontrolled and breaks through the basement of the acinus; then a malignant disease is present. Dr. Bloodgood is quite right in saying that this change has nothing to do with the original chronic cystic mastitis. There is no reason why such a breast, the seat of this involutional change, may not have a carcinoma growing in it which occupies the same relationship to it which it would to an unchanged normal breast; a tumor begins to grow in one, and for exactly similar reasons and causes, a tumor begins to grow in the other. Are we right in assuming that the involutional change is the cause of the neoplastic disease? The presence of the former need not necessarily be predisposing to the latter. And it is not at all certain that it is so.

Here is where our efforts must be directed. Progress in this dread malady has heretofore been perceptible because of a change in the attitude of the laity which causes the patient to consult the doctor much earlier in the course of disease; because of a greater diffusion of diagnostic knowledge among medical men, and because of increase of diagnostic acumen; because the patients coming earlier and earlier to us there is a progressive increase in operability; because of improvements in operating technic and ability; and because of the additional help of radium and the x ray. Progress hereafter must come from a knowledge of the causes, mechanism and biological phenomena of neoplastic growth. In these respects we doctors must be further educated; in these respects progress will henceforth be made.

Dr. Leo B. Meyer (in closing): Dr. Bloodgood, in his discussion, says that patients are referred to him so promptly after the onset of trouble with their breasts, that he finds sixty per cent. of the growths benign and only forty per cent. malignant. I am sorry to say that in my practice the reverse is true. Over seventy-five per cent. of the cases seen by me are malignant. Dr. Bloodgood's percentages speak well for the influence his teachings have had on those that come within reach of them. We are all hoping for the day when not sixty but seventy or even eighty per cent. of breast tumors examined by us will be benign, and this day will come when women will learn to consult their physicians as soon as they feel a lump in the breast. The nearer we get to this day the greater will be the surgeon's responsibility, as the differential diagnosis will be more difficult, almost impossible clinically and often doubtful after the exploratory operation, even with the aid of a frozen section. Dr. Bloodgood emphasizes the fact that when at the exploratory incision the naked eye appearance and the frozen section leave you in doubt what to do, the radical operation for cancer is best for the patient. This may result in some unnecessary radical operations where a less extreme one might have been sufficient, but there will be fewer (there should be none) incomplete operations for cancer. With this dictum I am in absolute accord. Thus far I have done no radical operation for benign lesion, but some day no doubt I will do one. When this occurs I shall certainly feel pretty bad, but not as bad as I would at doing a minor operation for cancer.

In my paper I have dealt mainly with the problem of how to shorten the time between the discovery of the growth and the visit to the surgeon. What is done after the surgeon has examined the patient is a question for his judgment. Whether to do a complete radical operation in large ulcerating cancers of the breast without axillary involvement, treating the axilla with x ray after the operation, must in the last analysis be up to the surgeon. I go one step farther than Dr. Lilienthal here; I think that even if there is axillary involvement, it might be advisable to remove the ulcerating mass without touching the involved axilla, relying solely on the x ray to delay extension. This after all is nothing but a palliative operation and to discuss these matters in detail here would take us too far afield. As to the use of röntgenotherapy before and after operation, I have for the past year been using it. I am unable to say as yet whether there is any material advantage, but I feel that we should give the patient the benefit of every possible means for cure at our command. In passing, it is worth while mentioning that not all workers in this field are agreed as to its benefits. I remember reading the report of one of the large clinics abroad in which the results seemed worse in the series of cases treated preoperatively by x ray than in those that were not so treated. It is possible that with the new powerful machines being used now the results will be more worth while.

From the viewpoint of treatment it makes very little difference whether a breast tumor diagnosed as benign is more likely to become cancerous than normal breast tissue, or whether it harbors a quiescent clinically undiagnosable cancer from the beginning. Dr. Lilienthal and I agree that the growth should come out. In considering this matter it is worth while taking into account the psychology of a patient who has, let us say, had a benign growth in her breast for several years. If she is told that the growth is benign and is no more likely to become cancer than her other breast, she will feel so secure that should the growth change its character she will be more apt to put off consultation with her physician than if some change should occur in her other breast, so that even if we could be certain that a growth is benign, the best advice would still be to remove it.

There can be no question about the danger of lactation to a breast the seat of cancer; the engorgement due to lactation will increase the rapidity of dissemination. No one could disagree with Dr. Tilton that in a pregnant woman, once the diagnosis of cancer of the breast is made, operation should be immediate; to wait until after delivery practically dooms the patient. One should keep in mind always, however, that the difficulty of making a diagnosis of cancer of the breast in a pregnant woman is much greater than in a nonpregnant one, because of the size of the breast and the lumpiness which (while it may be present in any breast, and if present may render diagnosis more difficult) is exaggerated in the breasts of pregnant women.

I agree with Dr. Wilensky that all of us are in need of more knowledge on this subject. That we are not yet educated up to the point where we can always be positive that a given mass is or is not cancer is sufficient reason for our not being dogmatic in our preoperative diagnosis. True, our diagnostic ability is better than formerly, but it must improve much more to do justice to the patients who will consult us earlier and earlier as cancer education gets in its effect. The proportion of benign tumors will naturally grow larger and larger, and we surgeons must, if possible, develop our diagnostic acumen to a degree that will enable us to differentiate positively between a benign and a malignant growth. That stage we have not yet reached, and until we do, it is to the patient's benefit to lean towards apparent radicalism rather than conservatism when dealing with tumors of the breast.

Gastrointestinal Infections in Chronic Arthritis

By G. A. PERSSON, M.D.,
Mount Clemens, Mich.

TYPES OF ARTHRITIS.

Chronic diseases of the joints present a perplexing problem so far as classification is concerned. For the purpose of this paper it suffices to divide this group of diseases into two types. Type 1 is characterized by proliferation of the synovial and lymph marrow, causing degeneration of the bones and cartilage. Type 2 is characterized by degeneration of the synovia and lymph marrow, causing hypertrophy of the bones and cartilage.

The first type includes clearly defined infections of the bones in tuberculosis and syphilis. The second type is sharply differentiated from the first and includes what is known as arthritis deformans, or osteoarthritis, or degenerative arthritis. This type has also been designated by some authors as hypertrophic or metabolic and senile arthritis. It is not infrequently found in the elderly in the form of Heberden's nodes or nodules of the terminal interphalangeal joints and in this form is often confused with gout.

CLINICAL DATA.

Beginning with March, 1910, and continuing until May 31, 1922, we had occasion to study the relation of gastrointestinal infections to arthritis. The series of cases observed in this way and here reported falls under the second of the types described above, thus excluding tuberculous and venereal infections. During this period 2,973 cases in all passed under our observation. The ages of the patients ranged from twenty-three to eighty-five years, eighty-seven per cent. being over thirty-five years of age. In classifying these cases we for convenience divided them into two groups, one, which we termed the upper zone, including infections of the mouth, nose, and throat, and the other, which we termed the lower zone, including infections of the intestines and their appendages.

During the first four years of this investigation, i. e., from 1910 to 1914 inclusive, patients having infections of the upper zone only represented fourteen per cent. of the cases observed, patients having infections of the lower zone only represented fifty-eight per cent. of the cases observed, and patients having infections of both zones represented the remaining twenty-eight per cent. From 1914 to 1922, inclusive, of the patients observed fifteen per cent. had infections of the upper zone only, sixty-three per cent. had infections of the lower zone only, and the remaining twenty-two per cent. had infections of both zones. The results obtained in these two periods are cited separately for the reason that our technic in connection with the isolation of streptococci from the cecocolon was improved during the second period and that during this period the patients observed had received better attention to nasal, tonsillar, and dental infections. Thus, while the figures, as given above, indicate an increase in the percentage of lower zone cases during the second period, this may well enough be due to these two contributory factors.

Of the entire number of patients who came under our observation during these twelve years sixty-nine per cent. reported that they had had operations in the upper zone (nose, tonsils, teeth, etc.) in order to remove focal infections. Of these, twenty per cent. reported that they had experienced a marked improvement in arthritic conditions, thirty-six per cent. reported a slight improvement, and forty-four per cent. were apparently worse, i. e., they gave histories of more frequent and severe attacks of arthritis, often in joints never before affected.

The facts here stated regarding the clinical results following surgical treatment of focal infections in the upper zone are not offered as a criterion of the efficiency of surgical means in such cases. It is a logical inference that patients who were either cured by such means or experienced marked relief from them had no occasion to seek further treatment and therefore did not come under our observation. It is also evident from our figures that while sixty-nine per cent. had had upper zone infections, only forty per cent. had them at the time they came to us.

It is, however, obvious from the same figures that surgical procedures in the upper zone, while effective locally, are often effective only for the time being so far as the general condition is concerned. The operation removes the focus, it is true, but it does not remove all the invading bacteria, usually leaving some few stragglers to start a colony elsewhere that will become an active source of infection later on under conditions favorable to its development. If we assume, as we reasonably may, that these offending organisms are members of the elusive family of streptococci, it at once becomes apparent that the failure of surgical measures in such cases is due either to the fact that the focus removed, such, for example, as a dental abscess or diseased tonsils, was not the only one where these invaders had entrenched themselves or else to the fact that the operation was unsuccessful so far as complete elimination of the invading bacteria was concerned.

ELECTIVE LOCALIZATION AND THE OPSONIC INDEX.

In our study of this series of cases the opsonic index was used as a criterion of the patients' resisting powers to streptococcus. Early in our investigation in this direction we were confronted with an interesting problem. A marked variation was observed in the opsonic index in relation to different strains of streptococci. For example, strains isolated from dental abscesses, infected tonsils, diseased gallbladders, and other particular locations, brought out marked differences in opsonic response on the part of the patient. The quality of this response was sometimes vigorous, sometimes merely fair, and sometimes negligible or even entirely negative. As our investigation proceeded it became increasingly evident that a selective force of some kind was at work, that affinities existed between strains of bacteria isolated from the same location in different persons. Cecocolon streptococci responded to those from the cecocolon, tonsillar to tonsillar, and so on. We finally demonstrated the fact that this selective peculiarity amounted to a definite law.

We therefore made the computation of the opsonic index to strains of streptococcus isolated from different locations a part of the routine procedure of examination in all arthritic cases and by this means were usually enabled to determine the location of the focal infection. The procedure employed was as follows: First, recently isolated strains of streptococcus and bacillus coli from definite anatomical locations were taken and employed as stock cultures. These locations in the case of streptococcus were 1, tonsils; 2, dental abscess; 3, gallbladder; 4, cecocolon; 5, prostate; 6, uterus, and, 7, urinary bladder. These organisms were cultivated in acetic glucose broth and transplanted frequently. The strains of bacillus coli were isolated from, 1, the cecocolon; 2, the gallbladder, and, 3, the urinary bladder. These organisms were cultivated on plain agar and classified according to the fermentation test on manite, lactose, and salicin. The opsonic index for these different strains of bacteria was computed according to Wright's method.

From the data gathered from this procedure we found that the patient usually exhibited a low resisting power to one particular strain of streptococcus. There were exceptions to this, some patients exhibiting such low resistance to strains from three or four different locations. These were classified as multiple infections. In the great majority of cases, however, a low opsonic index was registered for one strain only. A specimen was then obtained from the particular location indicated, for example, if the patient's opsonic index registered low to gallbladder streptococcus, a specimen was obtained from his gallbladder by duodenal drainage. If the low resistance was to a cecocolon strain, a specimen was obtained from that source by means of colon drainage, and so on. This specimen was planted in acetic glucose broth and cultivated for six hours. About one c. c. of this culture was then inoculated intravenously into a laboratory animal (rabbit), which was sacrificed after forty-eight hours. A postmortem examination usually revealed a focal infection in the animal in the location corresponding to that of the infection in the patient. From the lesions in the animal the organism was obtained in a pure culture.

INFECTIONS OF THE CECOCOLON.

Returning to the question of location, it has been noted that the majority of the cases we had under observation showed infections of the lower zone. These infections were for the most part in the cecocolon, which would indicate that this is the location most favorable to streptococcus cultivation. As is well known there has been a great deal of discussion as to the reason for the presence of pathogenic streptococci in the lower intestines and also as to the relationship between such streptococci and those in the oral cavity, in view of the fact that cecocolon infections by streptococcus are so frequently preceded by oral infection due to the same type of organism. The theory has been advanced that these organisms travel by way of the alimentary canal from the mouth to the intestines and there effect an entrance through the mucous membrane into the deeper tissues. It is a well established physiological fact that the normal mucous membrane of the intestinal tract offers marked protection against the inroads of bacteria. Any break in its continuity, however, or increased permeability due to trauma or other causes, affords a ready entrance for these microorganisms. In the opinion of others pathogenic bacteria are transmitted from focal infections in the oral cavity to the intestines by way of the bloodstream. The question might be raised as to why, if these bacteria are thus carried by the bloodstream, a general septicemia does not result or why focal infections are not simultaneously set up in other parts of the body. The answer to this lies in the elective localization of these bacteria, which causes them to select the intestinal canal as their habitat. This predilection may be explained by the somewhat similar conditions existing in the mouth and the intestines. Rosenow has demonstrated experimentally with rabbits that intravenous injections of streptococci isolated from lesions of the appendix are followed by marked localization with corresponding lesions in the inoculated animals. On the other hand he was unsuccessful in producing appendicitis by way of the mucous membranes unless the blood supply of this region was markedly interfered with. Whether one, or the other, or both of the theories discussed be true, the fact nevertheless remains that bacteria tend to change their characteristics with their environment and to develop special affinities for those locations in which they have cultivated themselves for a certain length of time. While strains of bacteria from different locations are microscopically identical their biological functions differ materially with their environment. This difference of function may well explain the variations of the opsonic index.

The fact that the intestinal tract of a newborn child is sterile, but becomes infested with bacteria in a few hours, coupled with the fact that the life history of the child repeats in many respects that of the race, tends to show that the alimentary canal, and particularly the colon or large areas of it, was the original seat of focal infections and consequently is today the most vulnerable point to the invasions of pathogenic bacteria.

Ewings's pathological report of a great number of cases of colon infection shows the presence of definite gross anatomical lesions, such as pigmentation of the mucosæ, which was most frequently evident in the sigmoid portion. This was often associated with thinning of the intestinal wall in places and with erosion and ulceration of the mucosæ. This condition would readily permit the absorption of toxic fluids and pathogenic bacteria that would lead to general toxemia resulting in the disturbed metabolism that is so characteristic of arthritic patients.

FORMS OF TREATMENT.

The treatment of arthritis naturally divides itself into three objectives: 1, the elimination of focal infections; 2, the elimination of toxic substances produced by faulty metabolism; and, 3, the restoration of glandular efficiency.

REMOVAL OF FOCAL INFECTIONS.

The removal of focal infections is by far the most important of these procedures. Owing to the fact that the location of such infections is frequently obscure the treatment of arthritis has in the past been somewhat unsatisfactory. In the case of infections that are definitely located surgical removal is indicated when the focus is so situated as to render this possible. When the conditions are not operable immunization of the patient should be resorted to by inoculation with specific bacterial antigens.

By specific is meant a bacterial antigen produced from a particular strain of bacteria isolated from lesions in the human body which involve tissues or structures to which this particular strain has a peculiar affinity. The elective localization of bacteria is not new. It is well known, for example, that pneumococcus elects to locate in the lungs, gonococcus in the urethra, the typhoid bacillus in Peyer's patches, and so forth. Furthermore, even among those species of microorganisms whose distribution is more general, such as streptococcus, staphylococcus, and bacillus coli, we find that certain strains have a specific affinity for definite tissues and organs. Rosenow has demonstrated this peculiar inherent property of bacteria and proved by his experiments that intravenous injections of specific strains of bacteria into laboratory animals usually result in the development of lesions in the animals in the regions corresponding to those from which these strains have originally been isolated. Our own investigations from 1910 to 1922, inclusive, confirm his findings and indicate that in the study of elective localization lies the key to a more scientific application of bacterin therapy, which should result in the bringing about of more uniform immunizing response.

The responsiveness of the human economy to certain strains of bacteria by which it happens to be infected is not unlike that of a wireless apparatus to currents of a certain wave length. It would seem that when focal infections caused by a particular strain of microorganism are established in any part of the body, the system becomes much more responsive to that strain than to any other, just as a wireless outfit may be attuned to respond to waves of a given length and to those exclusively. The inherent tendency of all bacterial life to change its characteristics in the process of adapting itself to its environment produces these selective local strains and tunes up the body, so to speak, to respond to them, when introduced from without, by an immediate production of suitable antibodies. Prophylactic and therapeutic immunization with specific bacterial antigens is based on this inherent tendency of microorganisms and the brilliant results often secured may be directly ascribed to our ability to take advantage of this natural law.

ELIMINATION OF TOXINS.

The elimination of toxic substances produced by faulty metabolism may take place in several ways. The avenues of elimination are the intestinal tract, the kidneys, and the skin. All three of these should be taken advantage of. The intestinal tract may be emptied by the administration of suitable cathartics, but it is generally more advantageous to employ duodenal or transintestinal lavage or free colon drainage. By these means the entire alimentary tract can be relieved of offending substances. After the intestines have thus been cleared, lactic acid bacteria may be introduced in order to change the character of the intestinal flora. The activities of the kidneys may be increased by mild diuretics, of which there is nothing better in most cases than pure water taken in sufficient quantities. The excretion of poisons through the skin may be stimulated by hydrotherapy. In this connection mineral baths have proved of considerable value. While the action of such baths is not as yet definitely understood, it is known that they act not only as stimulants to the skin but also produce an alterative effect. These effects may be due in part to the radioactivity of certain waters and in part to their constituent mineral salts. It has been proved that while the patient is in the water these salts are deposited on the skin and gain entrance into the pores. The minute deposits thus created cause first a stimulation and then a general counter-irritation, thus increasing the superficial circulation. They also lead to complex chemical changes that we have not the space to describe, which are alterative in their action.

GLANDULAR UNBALANCE IN ARTHRITIS.

Glandular insufficiency in its relation to arthritis is a subject that is considerably misunderstood and also considerably underrated. We have already pointed out that focal infections of the alimentary tract are present in a large majority of arthritic cases. These infections are probably of long standing and represent a losing battle on the part of the system against the inroads of invading bacteria. This battle begins in infancy and turns toward defeat at that period of life when, owing to the strain of the exacting conditions under which we live, the toxins created by inimical bacteria accumulate to such a degree that they give rise to glandular unbalance. This occurs because the glandular secretions poured into the blood that stimulate the development of antibodies finally become insufficient for the performance of their functions, owing to the excessive demands upon them. Certain of the overloaded glands tend to exhibit alteration of physiological function and their secretory power becomes curtailed. This at once impairs the efficiency of the particular organs that are normally kept at par by the presence of these secretions carried to them by the bloodstream. This impairment weakens the resisting power of the organs concerned, which thus fall an easy prey to the inroads of bacteria that in turn tend to weaken them still further. A vicious circle is thus created that works always for more and more unbalance in the interlocking system of glands that controls our vital processes and that presents a constantly diminishing check to the inroads of pathogenic bacteria.

It is now known that upon the appearance of bacteria in the bloodstream the toxins created by them give rise to a defensive reaction in the body as a whole. This defensive process appears to be as follows: The presence of toxins in the blood excites the thyroadrenal centre, thus giving rise to secretions that have the effect of increasing oxidation and metabolism throughout the tissues and of producing an excess of phagocytes of a peculiarly aggressive type. The red blood corpuscles are also stimulated to the secretion of opsonins and amboceptors, which have the effect of softening and sensitizing the invading bacteria, which are then ingested by the phagocytes and digested by the trypsic ferments.

Inasmuch as each gland in the body secretes a fluid that, carried by the bloodstream to some other gland or organ, stimulates such gland or organ to its proper degree of activity, a diminution of the normal secretory power of any gland necessarily makes for unbalance, as we have shown. When the focus of infection has been removed and the toxic substances that produced disturbed metabolism have been eliminated the affected gland often fails to resume its physiological function. It then becomes necessary to administer the lacking secretion in the form of a glandular extract until the gland returns to normal.

The routine procedure followed in our treatment of these arthritic cases, and still practised in such disorders, begins with the locating of the focal infection. Certain facts in the patient's history serve as a guide to acute infectious processes from which he has suffered in the past. Physical examination gives certain indications in the present. The opsonic index is then computed with reference to particular strains of streptococcus isolated from various locations known to be frequently infected, as dental abscess, tonsils, gallbladder, cecocolon, and prostate. This usually points to a definite location as the site of the infection. When possible the infecting organism is then isolated from this particular location in the patient and an antigen is prepared therefrom, with which he is immunized. The initial dose is usually one half c. c., which is repeated every twenty-four hours, being gradually increased until one c. c. is reached at the end of nine days. A second opsonic index is then taken to check the patient's progress. Daily inoculations of one c. c. are given thereafter until the opsonic index, which is taken every nine days, reaches normal. After this inoculations are given every three days for three or four weeks, in order to raise the patient's resisting power to a high level. Our records covering a twelve year period show that the length of time required for immunization ranges from thirty-six to sixty-nine days, with an average of forty-seven days.

The clearing of the alimentary tract is usually accomplished by free colon drainage and the administration of suitable laxatives and intestinal antiseptics. The colon drainage is given daily for about twenty days, then every second day during treatment.

Hydrotherapeutic treatment is given daily in the form of mineral baths. Local applications to the affected parts are made when indicated. This is accompanied by massage, electrical treatment, and mechanotherapy when required. Free diuresis is produced by encouraging the patient to drink considerable quantities of water at frequent intervals.

All the measures described are carried out simultaneously from the beginning of the treatment. The administration of glandular extracts as a means of restoring glandular balance begins during the progress of the treatment at a point determined by the rise of the opsonic index. When the index falls below the normal curve exhibited in arthritic cases under treatment the administration of glandular extracts is begun. If the curve remains normal to the end of the treatment the extracts are not employed. After immunization is completed, however, glandular extracts are always administered in small doses for some weeks, with an intermission of about the same length, when the process is repeated anew, continuing as a rule for some months.

It may here be noted that the administration of monoglandular extracts is usually much more effective than the hit or miss method of giving polyglandular preparations. Specific therapy is here indicated just as clearly as in the case of bacterial antigens. By stimulating the particular gland that is at fault the glandular balance of the body as a whole tends to be restored. Polyglandular extracts, on the other hand, tend to overstimulate some glands while raising others to normal efficiency and may produce complications due to the substitution of one form of glandular unbalance for another.

The amount of food consumed in chronic arthritis is a very important matter. The patient should be restricted to some extent in his normal consumption of food, in order to facilitate complete metabolism. Our records show that the average arthritic patient consumes from twenty-eight hundred to three thousand or more calories a day. Such patients can be reduced to two thousand calories a day and still maintain good nutrition. In order to provide the necessary bulk under this régime a plain diet is indicated rather than a rich one.

The routine treatment described above produced satisfactory clinical results in the great majority of cases in the series we have discussed. We hope in a future paper to analyze certain typical conditions and also certain specific peculiarities in arthritic patients which have led to the development of special therapeutic measures that have proved effective.

The Significance of the Spinal Mercurial Manometer*

By A. S. MACLAIRE, M. D.,
New York.

The spinal mercurial manometer is unknown and unheard of by most physicians and many of the large hospitals in New York do not possess the apparatus. Even many neurologic surgeons do not employ it in their work where it is of greatest value.

The spinal mercurial manometer is today undergoing the same trials and tribulations that the blood pressure apparatus suffered thirty years ago. What physician at present fails to record a blood pressure reading before he completes his physical examination and renders his diagnosis? Yet the neurologist and neurosurgeon are contented to regard their examinations as complete without an accurate intracranial pressure reading. At the same time they demand accurate blood pressure findings. Their reasoning and logic are as fallacious as the former clinician who opposed the blood pressure apparatus.

Today the neurologist and the neurological surgeon do not deny the importance of the knowledge of the presence or absence of increased intracranial pressure, but they attempt to estimate it roughly, judging from the spurt of the spinal fluid as it rushes out from the lumbar puncture needle. If the fluid exudes drop by drop it is evidently not under pressure; if it comes out in a stream, then of course it is under pressure; but what degree of pressure they do not know. Accurate readings are essential if we are to treat cases to the best advantage of the patient. How else are we to determine scientifically when a case is to be treated by expectant measures, or by operative procedures? This becomes of utmost importance in traumatic brain injuries. The method of most neurologists and neurologic surgeons in determining intracranial pressure parallels the method employed by the former opponents of the blood pressure apparatus. The old clinician estimated his blood pressure with his finger on the pulse. A full, bounding pulse indicated high pressure, how high he did not know. No one today will presume to say that to determine blood pressure by means of touch is unreliable, yet neurologists and neurosurgeons are using a similar method when they do not use a spinal mercurial manometer for intracranial pressure. Both tests and devices are similar, one being for blood pressure and the other for spinal fluid pressure.

We are now in an age of medicine and surgery where we are constantly striving for early diagnosis and early institution of proper rational therapy. Here is such an apparatus for the neurologist and neurologic surgeon, yet they disregard it. I recall vividly two cases occurring recently in two of our large New York City institutions, in which operation was delayed several weeks because of uncertainty in diagnosis, where the fundi failed to reveal the desired information of increased intracranial pressure and where the spinal manometer would have decided the issue had it been employed. To wait for choked discs to occur is as bad neurological surgery as it is in general surgery to allow an appendiceal abscess to form before operating. Choked discs signify a greatly increased intracranial pressure over a prolonged period. The manometer detects early rises in pressure and can be closely watched by repeated readings. It is true that in a slowly growing intracranial neoplasm the changes in intracranial pressure are not as rapid as in traumatic cerebral conditions, nevertheless they do occur. Instead of daily manometric readings, as in the traumatic cases, readings are taken once or twice a week in brain tumors when the slightest rise in pressure will be detected early. No fear need be entertained for medullary injury in puncturing the subarachnoid space, for no fluid need be lost in this test. No fluid need be removed. This method will obviate the undesirable secondary optic changes that occur in choked discs.

The cases referred to above were as follows:

Case I.—This was a case of left cerebellar pontine angle tumor without changes in the fundi. To me it appeared like a clean cut cerebellar pontine angle tumor, as it did to the operating surgeon on service, yet two neurologists made the diagnosis of multiple sclerosis, because of the absence of choked discs. The spinal mercurial manometer would have supplied the information the two neurologists were seeking. At operation a left cerebellar pontine angle tumor was found.

Case II.—This case, at another hospital, was a left hemiplegia with indefinite sensory findings on the same side. The fundi examined on several occasions by two ophthalmologists gave differences in opinion at each examination. At no time did they concur in their findings. There was uncertainty as to obscuration of the disc margins and beginning engorgement of the veins. Normal fundi were finally reported by the attending ophthalmologist at the last examination. At operation a huge endothelioma was disclosed and removed. The spinal manometer would certainly have been a great aid here in the diagnosis of increased intracranial pressure. The blood pressure was misleading in this case, not being much elevated, proving that the blood pressure is a poor indicator of early changes in increased intracranial tension.

Especially in traumatic cerebral surgery are spinal manometric readings essential. In a recent case of fracture of the base of the skull (1), occurring in one of our large hospitals not equipped with a spinal manometer, the condition was permitted to drift from the initial stage of shock into that of medullary compression and eventually of medullary edema before calling in the consulting neurological surgeon to operate. To those specializing in neurological surgery it is selfevident that when a case reaches the stage of medullary edema operative procedures are absolutely contraindicated. In such cases death almost invariably supervenes, either with or without surgical intervention. I do not wish to imply that every patient operated upon before medullary edema sets in survives, but I do wish to emphasize the fact that patients with increased intracranial pressure of

15 mm. Hg. or over, if operated upon early enough, have at least the best chances for recovery, not only of life but of future normality. Those with a pressure under 15 mm. Hg. may be treated expectantly by repeated lumbar tappings and the removal of fifteen to twenty c. c. of fluid until the pressure reaches the normal 5 to 9 mm. Hg.

The excuse given at this hospital for its negligence was that under expectant treatment the high shock pulse came down to normal and continued to drop to 60 and lower. The blood pressure came up from the low shock pressure to the high blood pressure of over 160 mm. Hg. These two signs are late indicators of medullary compression. Had the spinal manometer been used routinely after the recovery from shock, operative intervention could have been instituted at a time when the patient could have been given a chance for ultimate recovery. As it happened, the patient was left to cope with the situation himself and medullary edema occurred. Not all cases of medullary edema are fatal. Rarely recovery as to life takes place, but the patient is left either emotionally or physically impaired. He complains of those symptoms which stamp him as suffering from a posttraumatic neurosis, whereas in reality he is suffering from the effects of a prolonged increased intracranial pressure.

One cannot any longer hope to perform brain operations, especially traumatic brain surgery, intelligently and scientifically, without the use of the spinal mercurial manometer. In its wider adoption many needless deaths will be prevented.

An Appraisal of the Newer Methods of Deep Röntgen Therapy*

By JAMES T. CASE, M.D.,
Battle Creek, Mich.,
Surgeon and Director of the Radiological Clinic, Battle Creek Sanitarium, Professor of Röntengenology, Northwestern University Medical School (Chicago).

In this effort to review the present situation regarding deep x ray therapy and to make an appraisal of its value I shall refer only in passing to the advances recorded in a number of benign conditions, such as hyperthyroidism, uterine myomata, ununited fractures, tuberculosis, various forms of neuritis, chronic arthritis, especially that due to gonorrhea, prostatic hypertrophy, hypertrophied and infected tonsils and adenoids, as well as in a number of conditions where it is hoped that the effect of the modified dose administered will be the stimulation of certain processes (socalled irritating doses); my remarks at this time will be confined to the employment of röntgenotherapy in deep seated malignant disease.

The basic principles which underlie the newer methods of deep röntgenotherapy may be set forth briefly as follows: First of all, one must have a generating apparatus capable of sending constantly and continuously through the x ray tube a current at hitherto unprecedented voltage 200,000 or more. It has not yet been demonstrated that higher voltages than this are perceptibly more useful or more desirable, but if it should prove that they are, there is no reason why they cannot be made available. This high voltage through the tube produces x rays of relatively shorter wave length and correspondingly increased penetrating power, more and more approaching that of the gamma rays of radium, though by no means reaching the gamma figures. Dessauer is responsible for the statement that the absorption coefficient of the röntgen rays, as expressed by μ for water, is 0.7 for the medium soft diagnostic rays; 0.26 for the medium hard diagnostic rays; 0.21 for the hard diagnostic rays; 0.18 for the deep therapy rays of six or seven years ago; 0.155 for the hard rays of 1918; and 0.134 for the best German equipment of 1920; whereas for gamma rays of radium μu (water) is 0.043.

It is evident that marked progress has been made in producing more penetrating röntgen rays, and that we may look upon the radiation provided by our present 280,000 voltage apparatus as closely approximating, in penetrating power, the gamma rays of radium.

Naturally, the higher penetrating power of the new rays permits the use of denser filter materials; and the application of the electroscope and the ionization chamber to the study of these problems permits the determination of the exact amount of filtration necessary to produce a practically homogeneous radiation. It seems from present knowledge of the subject that there is proportionately little advantage to be gained by filtration through more than a half millimetre of copper or zinc plus 3-4 mm. of aluminium, though I have for nearly two years employed a filter of one millimetre of copper plus ten millimetres of sole leather. Studies leading to this conclusion have been made with currents of not higher than 200,000 volts delivered to the tube.

Elucidation of the once perplexing question of scattered radiation and the success of the ionometric methods of measurement of the actual amount of radiation arriving at a given depth in the tissues have made plain two other important conditions for the new röntgenotherapy, viz.: 1, long distance radiation, placing the focus of the tube at from fifty to one hundred cm. from the skin, and 2, the employment of larger fields (ports of entry), thus taking advantage of the proportionately increased scattered radiation, materially increasing the dose of x ray absorbed in the depths of the body.

In the absence of ionometric determinations, it is thus necessary, in recording röntgen rays application, to specify six factors: 1, voltage through the tube; 2, milliamperage; 3, filtration; 4, target skin distance; 5, size of field; 6, time of treatment.

---

*Read at the annual meeting of the New York Academy of Medicine, January 5, 1922.

No attempt will be made in this paper to describe the technic of application. Each case must be studied individually, and the plan of campaign mapped out after careful consideration of the extent and anatomical location of the malignant, or potentially malignant, tissue it is necessary to reach. Whether one will employ multiple fields on the crossfire principle, with relatively short focus skin distance, or one or two fields at very great target skin distance, will depend on the case. The deeper the lesion, the uterus for instance, the more appropriate will be the crossfire method, and the more favorable the prognosis; the nearer the lesion to the surface, the breast for instance, the more difficulty in delivering a sufficient radiation dose, and the more likelihood of succeeding with a longer distance, large field irradiation.

Permit a reminder that sufficient time has not yet elapsed for the observation of cases for the usual five years since treatment by the refined methods outlined above. Indeed, scarcely two years have gone since the wide adoption of this technic. Yet results thus far obtained, concerning the reliability of which there is no gainsaying, warrant a certain amount of pardonable enthusiasm in the pursuit of this path of inquiry, and a decided optimism in the outlook for the future of deep röntgenotherapy in certain cancers, which, though inoperable, have not yet progressed to the stage of cachexia and metastasis.

It would seem to the "lay" physician that we have almost reached the limits of possibility in the physical measurement of x ray doses. What we need most is a biological standard easily recognized by various workers with which our physical estimations may be collaborated. Important work has been done by such investigators as Wood and Bovée in this country, Regaud of Paris, and their associates; and we expect them to furnish the next step necessary to a rational basis for the radiation therapy of cancer.

It is true, a sort of biological standard has already been proposed, and it is the only one we are able to employ at present, viz., the skin erythema dose. Upon it is based all the work of the Freiburg, Erlangen, Frankfurt, Berlin, and other German schools of modern deep therapy. It is the one reaction in the limelight in radiotherapy all these years; yet so varying are the conceptions of different men as to what reaction marks a skin erythema dose, that there must be opportunity for wide divergence of opinion in calculating the dose delivered to deep seated lesions. One school understands an erythema dose to signify that amount of x ray which will within nine to fourteen days be followed by a slight reddening of the skin, and in four weeks by a definite brown pigmentation. Another school conceives the erythema dose to involve a much more pronounced reaction, with vesiculation of the skin. Regaud, of Paris, defines a proper skin reaction as characterized by an almost dry radioepidermatitis, with desquamation, renewal of the skin in about fifteen days, and finally often a blanching of the skin in place of a pigmentation. Experienced radiologists are also well aware of different radiosensitiveness of the skin of different parts of the body. Decidedly, a better and more constant biological standard is desirable.

Based on the rather unstable skin erythema dose, efforts have been made to establish the carcinoma dose, the sarcoma dose, the castration dose, and the other biological doses, especially by German workers (Kroenig and Friederich; Seitz and Wintz; Halberstaedter; and several others). The figures given by Kroenig and Friederich are lower than those of Seitz and Wintz, but the differences are explained by their different conception of the reactions characterizing a skin erythema dose. Faulty as it may be, the familiar table of Seitz and Wintz constitutes our best guide at the present writing, and is therefore reproduced here:

Skin erythema dose..................	100 per cent.
Ovary castration dose.................	34 per cent.
Sarcoma dose	60-70 per cent.
Carcinoma dose	100-110 per cent.
Rectosigmoid dose	135 per cent.
Muscle dose	180 per cent.

These authors consider the skin sensitivity as varying not more than ten to fifteen per cent.

Naturally one questions at once the possibility of a sarcoma or cancer dose being established at any given percentage of skin dose, not only on account of the inconstancy of the skin erythema as a standard, but also because of the long recognized difference in radiosensitivity of a lymphosarcoma, for example, as compared with a sarcoma of periosteal origin; and possibly the somewhat less variability in the reaction of the various types of carcinoma to radiation. Yet we must not pass over lightly the published results of the more important German radiologists which I have personally verified in scores of cases. Seitz and Wintz specifically state that they observe little difference between the response of carcinoma, whether scirrhous or medullary, possibly on account of the shorter wave length of the radiation they employ, though we have observed considerable difference in this country, employing radium, with its still shorter wave length gamma radiation. We must receive the Seitz and Wintz figures with some skepticism, therefore; yet to date their figures serve as our working basis, and we should not stint our praise of their work.

A big question mark stands opposite the proposition to administer the carcinoma dose within the shortest possible time. A wide divergence of opinion is noted on this point. Some of the leading German deep roentgen therapists urge that the entire dose be given at one sitting, or within two days at the most, the sessions totalling from nine to fourteen hours of actual subjection to radiation. Others, as Seitz and Wintz, administer the full treatment of pelvic cancer, for instance, in three carefully planned but intensive sessions separated by six to eight weeks' interval. Still others, notably Holzknecht and Groedel in Central Europe, and Béclère and Regaud in France, take issue with the intensive single session, massive idea. Regaud especially recommends much weaker doses (both of radium and x rays) extended over seven or eight days and believes that he and his associates have proved the advantage of this more deliberate plan. After as extensive observation as possible, both of my own work and the work of others, I choose to prescribe for my patients the full dose within the shortest reasonable time, considering the comfort of the patient, and endeavoring to complete the delivery of what we consider the probable carcinoma dose within four to eight days, including both x rays and radium when the latter is appropriate.

With the exception possibly of a few institutions richly supplied with radium, the attack on malignancy will probably be best accomplished by röntgen rays from the exterior and by radium from the interior (mouth, esophagus, vagina, uterus, rectum, bladder, nasopharynx, and such lesions as may invite the burial of radium emanation). Of course, time will tell; this paper is an attempt at appraisal. In this connection, permit me to invite your attention both now and in the future to the work of a very earnest group of investigators headed by Regaud at the Radium Institute in Paris, working in connection with Madame Curié and Béclère and Ledoux-Lebard, whose efforts, less widely heralded and exploited than those of the German schools frequently referred to, will throw much light on both the technical and biological aspects of radium and röntgenotherapy.

As to postoperative röntgenization, we must recognize that radium alone has not proved sufficient in the postoperative treatment of malignancies. All are familiar with the clinical results obtained in this country and the divergence of opinion so recently aired in an important conference of surgeons. Brunn after eight years and Wertheim's clinic after six years of experience in the postoperative use of radium for prophylactic purposes, realized that the local use of radium did not suffice. The reason is easily comprehended, fór unless one has enormous quantities available for external "radium packs," the local application must be inefficient at a few centimetres depth. The new röntgen therapy with super x rays permits a homogeneous radiation with a combination of internal radium and external röntgen application calculated to give the best possible protection against recurrence after operation. This postoperative irradiation would appear to be a matter of an intensive single session treatment (dose given within one to four or five days). And if the admirable work of Bovée is to be applied to therapy, is not the preoperative röntgenization placed on a more reasonable footing than ever before? Naturally, one hesitates to administer a full erythema dose to skin which must be incised within a few days, for fear of endangering the healing of the wound; but even if the dose of radiation arriving at the malignant tissue is not sufficient to kill it, the work of Bovée gives us ground for belief that we have inhibited the power of division of the malignant cells and materially diminished the danger of transplantation of malignant tissue during the operative procedure.

Röntgen intoxication (irradiation sickness) is one of the least serious complications of the newer deep therapy, though it stands out as one of the most disturbing to the patient. Headache, nausea, vomiting and weakness are fairly common in a greater or less degree, but fortunately the symptoms are transient and usually disappear within forty-eight hours at the most. Many patients suffer during the first of the applications and are not at all inconvenienced during the remaining two or more days constituting the session. The röntgen sickness is, like sea-sickness, not yet adequately explained. It is almost impossible to foretell who will be sick. Some go through the whole session without inconvenience, while others appearing equally able to withstand minor symptoms are woefully upset for a day or two. Occasionally (especially after long distance irradiation in breast cases) the röntgen sickness lasts for weeks and is very disturbing to the patient, though after all of minor consequence compared to the malady we treat. Various theories have been advanced to explain the intoxication, for such it seems to be, disturbance of the internal secretion of the ovaries, or other glands of internal secretion; toxins developed in the intestines, especially the jejunum and ileum; disturbances of the sympathetics in the splanchnic area; acidosis; vitiation of the air of the room; absorption of products of disintegration of the tissue under radiation; changes in the blood (Heinecke). To all of these suggestions one immediately thinks of exceptions; and attention to any one fails to do more than slightly lessen the discomfort. One naturally chooses for treatment work a well ventilated room with high ceiling; he adopts a system of high tension wiring which minimizes corona; he puts his current generating apparatus in another room; he encourages the patient's eliminative processes in every possible manner; sedative drugs may be employed to minimize the nervous or psychic factors; certain endocrine therapy may prove useful. The ordinary tests for acidosis (estimation of carbon dioxide tension of alveolar air, study of the urine and the chemical analysis of the blood) in our clinic have failed to show evidence of acidosis even in cases subjected to the largest doses we have dared to administer, or in patients exhibiting most distressing symptoms of irradiation sickness.

When treated for lesions about the head and neck, the patients often complain of temporary dryness of the mouth and throat but the symptoms seldom persist for more than a day. Patients with uterine, rectal, bladder or prostatic malignancy frequently complain of rectal and vesical tenesmus, best relieved by radiant heat applied locally, warm sitz baths and sedative drugs. Incandescent light treatment may be applied within the vagina with gratifying relief.

The great danger with the super x ray treatment is no longer that of irreparably damaging the skin, but rather one of insufficient doses. Malignant tissues rapidly acquire a tolerance to radiation, which emphasizes the necessity for the single session application. Insufficient doses of radiation will probably serve to stimulate the very process we combat; hence the necessity for adequate dosage. Fortunately the shorter wave lengths of x ray energy are much less likely to damage the skin. The difference in skin effect between a bundle of long wave length rays and short wave length rays, the dose being equal, lies solely in the difference of distribution of the absorbed dose in the two cases. With the newer therapy, the skin absorbs relatively much less radiation than with our older methods.

To repeat, the greatest danger is in insufficient doses. I have seen no severe skin reaction in any case subjected to the high voltage röntgenization either in my own work or in the foreign clinics visited. A few, astonishingly few at that, late severe reactions have been observed, but in the future we should be able to avoid them, especially if we persist in the single session, massive dose idea. In certain cases subjected to repeated treatments with high voltage apparatus, induration of considerable skin areas may appear. If treatment of these areas is continued, late ulcerations may develop. These indurations are likely to occur only in advanced cancer cases, and any means of relief is justifiable in such an extremity. The harder the ray and the more intensive the treatment, the less the danger of skin damage.

Serious blood changes have been mentioned as a danger and an objection to the new method. We have heard of blood transfusions as more or less routine procedure in some clinics in connection with the high voltage therapy as a means of saving the patient from the "terrific" effects of the irradiation. In our own work we have carefully and repeatedly examined the blood of our patients subjected to the heaviest irradiation but no serious changes in the blood have been noted. The hemoglobin and red cell count have dropped slightly, not over five per cent. on the average, and they have returned to normal within a few days. The leucocytes have shown a transient increase, followed promptly by a drop of three or four thousand with a gradual return in a few weeks to the normal figure. There has been no occasion for blood transfusion except in a certain number of patients coming to the clinic with malignant disease so far advanced as to render them cachectic. Such patients are not suitable for treatment, anyway, and heavy irradiation may actually shorten the life of one whose days are already numbered. Certainly the most marked blood changes which have been observed are not permanent and they do not constitute a contraindication to the treatment, save in very cachectic individuals, as noted.

Intestinal disturbances may occur, and they usually do when the small intestines lie in the zone irradiated; looseness of the bowels may be disturbing for a week or two, but the symptom is rarely a prominent one. A more significant sign, and one which gives encouragement by demonstrating that the dose has been actually delivered into the deep tissues of the pelvis, is the late appearance of varices or even ulcerations in the rectum and lower sigmoid, easily demonstrated by proctoscopic examination. These may appear months after the treatment, but respond to topical applications. Similarly, vaginitis may follow the treatment, even when no radium or intravaginal röntgen applications have been made. Such rectal and vaginal erosions and varices are especially likely to follow heavy doses with local radium applications, and often cause perplexity in deciding whether or not one has to deal with a possible recurrence.

Are we likely to encourage metastases by our efforts at deep röntgenization? Surely no more than by radium treatment, if indeed as much. The work of Bovée, already referred to, would contradict this idea. It may be that the excision of small bits of tissue for biopsy may encourage metastasis; we need more light on this question. Does a diagnostic curettage before irradiating a uterine mass add to the patient's danger of metastasis? One wants to use radium within the uterus in such a patient in any case. Dr. Wertheimer, of the Frankfurt Frauenklinik, recently investigated the frequency of metastases in carcinoma of the uterus, comparing unrayed cases with a similar series subjected to radiation. In over a hundred cases included in the statistics, metastases developed in 69.2 per cent. of the unrayed women below forty years of age, and in 48.6 per cent. above forty; in the rayed cases, metastasis was found in 63.6 per cent. below forty, and in 44.0 per cent. above that age. Statistics show, it seems apparent, that proper administration of radiotherapy does not increase the development of metastases. It is difficult to put a proper estimate on the value of these figures, for naturally only cases which did not do well under radiotherapy were included.

Here it seems appropriate to speak once more of the danger of an insufficient dose of radiation actually producing a stimulation of the disease we are fighting. One of the most prominent gynecologists of Berlin (very conservative on the new röntgenotherapy), after admitting that from ten to twenty per cent. of the inoperable uterine cancers were apparently cured after two years and some a little longer, remarked that in the postmortem room they were now seeing occasionally a case where, in spite of heavy röntgen and radium treatment, the patient had succumbed. In these autopsies they were now seeing much larger malignant masses than formerly were found in similar cases before the days of deep therapy. This suggests a stimulation of the process through insufficient doses delivered to all the malignant cells.

Once again let us consider the apparent successes. No one is yet willing to speak too loudly nor too hopefully; sufficient time has not yet elapsed. In one of the two best known gynecological clinics of Berlin, an avowedly conservative surgeon operates in all operable cases but admits ten per cent. to twenty per cent. apparent cures in inoperable cases. On the other hand, in Freiburg, Opitz, Kroenig's successor, will operate in no case of uterine cancer, no matter how early. Opitz gave us his latest figures on ninety cases treated exclusively by x ray and radium by the new technic since January 1, 1919. They are given here in tabulated form, group I being early, easily operable cases; group II, more advanced, yet still operable cases; group III, inoperable cases, on account of broad ligament extension, and group IV, the utterly hopeless cases.

SIXTY CASES OF CANCER OF CERVIX AND PORTIO.

Group	*No. of Cases*	*Apparently Cured*	*Uninfluenced*	*Patients Died*
I	4	4	0	0
II	13	8	3	2
III	39	18	9	12
IV	4	0	1	3
Total	60	30	13	17

THIRTY CASES OF CANCER OF BODY OF UTERUS.

Group	*No. of Cases*	*Apparently Cured*	*Uninfluenced*	*Patients Died*
I	10	10	0	0
II	9	9	0	0
III	8	4	2	2
IV	3	0	1	2
Total	30	23	3	4

The Erlangen statistics are even more optimistic than those just cited. Seitz also had declared his decision to operate no more in cases of uterine carcinoma, no matter how early, but this decision is by no means generally accepted throughout Germany. The more conservative ground, coinciding with my own, is to operate in operable cases, but to do so in connection with carefully planned preoperative and postoperative irradiation, combining both röntgen rays and radium, according to the case. We do not feel that we should abandon surgery for carcinoma in its operable stage until more time has elapsed to permit us to draw trustworthy conclusions from the foreign clinics where the experiment of exclusive irradiation treatment is nearing completion of its five year period of watching.

Surely we would be as blind as the proverbial "those who will not see," if we fail to recognize the tremendous extent and importance of the work that has been done. We have ourselves seen favorable results with the new super x ray never equalled before. Palliative results have appeared more promptly than ever in a large percentage of cases. Some have responded no better than before. We have no right yet to talk of results, but we do consider ourselves justified in expressing the encouragement we feel in going earnestly ahead with our work, and the high hope that some, at least, of the apparent cures will prove to be permanent. If the good results do not prove to be permanent, they will at least be much superior to any previous accomplishment in the radiation treatment of malignancy.

Splenectomy for Traumatic Subcutaneous Rupture of the Spleen

By M. S. KAKELS, M.D., F.A.C.S,
New York.
Attending Surgeon, Lebanon Hospital.

The most frequent causative factor of a subcutaneous rupture of the normal spleen is severe traumatism to the left hypochondrium. This also obtains in spontaneous rupture of enlarged and diseased spleens although in the latter the traumatism need not be a severe one; a misstep, a slight blow or pressure from crowding, may be sufficient to rupture a distended capsule of a pathological spleen causing an exudation of the medullary pulp with attending hemorrhage. The severe traumatisms produce frequently at the same time complicated lesions which may involve adjacent organs. The character and the number of lesions depend on the nature, the direction of the force and the inflicting body.

The adjoining viscera which may be involved besides the spleen are the kidney, the left lobe of the liver, the greater curvature of the stomach, the base of the lung and the diaphragm. So we see, should any of these adjoining viscera be also involved at the same time, how the treatment of such multiple injuries may tax the resources of the operating surgeon. Therefore one ought to be sufficiently acquainted with the symptoms of lesions of the viscera situated in the left lower thorax or left flank to be able not only to diagnose but also to cope with conditions which may be met.

The indications for operative intervention in traumatic lesions of any of these organs are almost similar, but the nature of the operative procedures depends upon the organ involved and on the character of the lesion.

While considerable has been written concerning splenectomy for traumatism of the spleen every additional case may be not only of diagnostic value but frequently of aid in lowering the mortality in future similar cases. Recently I did a splenectomy for traumatic subcutaneous rupture in a child, the history of which is unique and the technic of the operative procedure and subsequent course of the condition interesting enough to be worthy of report.

Case.—The subject was a little girl eleven years old, who was admitted to my service in Lebanon Hospital on the evening of February 24, 1921, with a history of having struck a post four hours prior to admission, while bobsledding, injuring her left side. She could hardly catch her breath after the accident and immediately experienced severe pain over the lower left side of the chest anterior to the postaxillary line, and also in the upper left quadrant. There was no hemoptysis, but some pain on coughing. She vomited once after admission. There was no hematuria. She gave a history of having had a cough for about a week before she entered the hospital.

Her general condition seemed to be fairly good, although she was quite pale. The temperature was 98.8° F., pulse 78, and respirations 20. The eyes, ears, nose and throat were normal; the heart negative, and the lungs showed vesicular breathing throughout. There seemed to be a superficial friction rub over the left side about the region of the seventh and eighth ribs between the anterior and posterior axillary lines. Percussion revealed no abnormal dullness or flatness. The abdomen and chest showed no abrasions, but there was a noticeable resistance, especially at the upper left quadrant, in which region there was also considerable pain and tenderness. The liver was normal. The spleen was not felt and percussion over the organ showed no enlargement.

The next day the abdomen appeared slightly distended and this, with the partial resistance to the palpitating hand and pain and tenderness in the upper left quadrant, presented a suggestion of some peritoneal irritation. Although the pulse at this time was only 95, with no positive signs of internal hemorrhage, an injury of the spleen was nevertheless suspected, and orders were given to watch carefully for evidence of hemorrhage and that the pulse be taken every hour.

For twenty-four hours after admission there was practically no change in the temperature, pulse or respiration, and the rigidity in the upper left quadrant remained the same. On the following day, Saturday, February 26th, the abdominal distention was slightly more evident; there was tenderness over the left kidney region and left hypochondrium. The maximum tenderness was elicited on compressing the lower chest. Resistance over the entire abdomen was more marked, and the blood showed 3,500,000 red blood cells, 20,000 white blood cells, 50 per cent. hemoglobin, 98 per cent. polymorphonuclears, 10 per cent. lymphocytes, 1 per cent. transitionals. The pulse was 120, the temperature 100.8°, respiration 22. There had developed in the meantime an increased desire for water although there was not the slightest evidence of faintness or restlessness.

Operation was decided upon for the following reasons: Blood count, persistent rigidity in connection with pain in the upper left quadrant, tenderness and pain on pressure of the left lower ribs, evident distention, rapid pulse (120), pallor, nausea, suspicious dullness in left flank, and (what was of great significance in determining me to proceed) the nature of the injury in connection with these symptoms. Accordingly, at 8 p. m. under ether anesthesia, a vertical incision was made along the outer border of the left rectus which was later augmented by a transverse incision along the lower border of the ribs toward the left. On opening the abdomen there was at first no evidence of active hemorrhage, but on separating the coils of intestine fluid blood and clots began to appear. The spleen was immediately sought for and large clots were seen under the diaphragm and surrounding and covering it. On attempting to deliver the spleen active hemorrhage took place, and it was imperative to control the bleeding as quickly as possible in order to prevent an exitus. This was done by grasping the gastrosplenic ligament containing the vessels, with the fingers of the left hand until clamps were applied. The clots and the fluid blood were now carefully expunged and a better view of the parts obtained. A careful revision revealed several large and deep rents upon the surface of the spleen. The ligaments and adhesions were carefully ligated and broken down by finger dissection, and the lower and upper poles brought up into the wound. It was now seen that the organ had another large and deep tear running into the hilus which was covered by a large clot. The pedicle was ligated in two sections, and the entire organ delivered. The wound, after mopping and the placing of a small tampon on the oozing surface of the bed of the spleen, was closed in layers up to the gauze drain and dressing applied. The patient reacted very well from the operation, manifested a temperature of 103° on the evening of the second day, due to a postoperative pneumonia, signs of which appeared in the right lung. These signs gradually subsided to normal on the eleventh day, after which the little patient made an uneventful recovery.

Taking into consideration the extent and severity of the lesions in the spleen found at operation, the most interesting feature of this case was the comparative absence of symptoms of severe hemorrhage during the first twenty-four hours following the accident. In order to explain this condition one might assume that the adhesions present bound the spleen in such a way as to limit the flow of blood and thus favored clot formation, the gradual separation of this clot permitting a further active hemorrhage with all the evidence and signs of a continuous bleeding. That this assumption was correct was demonstrated by the large clot of blood found loosely connected to the spleen, after its delivery from the abdominal cavity.

Let us briefly survey the conditions which make it imperative to proceed with immediate surgical interference in lesions of the spleen.

Of first importance we would regard a subcutaneous rupture; secondly, penetrating wounds, such as stab or gunshot wounds, and, thirdly, traumatic prolapse or hernia.

Traumatic subcutaneous rupture is not an infrequent accident. Its symptomatology is not very exact, as the signs cannot be sharply differentiated from those resulting from injury to other abdominal organs, and to conclude that a rupture exists one must be supported by the evidence of two important factors, the first of which is symptoms of an internal hemorrhage and peritoneal irritation, and the second, a history of severe traumatism to the base of the thorax in the left hypochondrium, or in the left flank.

We would lay great stress on the importance of these two factors and regard them as the two cardinal points in making a diagnosis, and, furthermore, would not hesitate to state that if these two noteworthy facts can be elicited that they are more than presumptive evidence of rupture of the spleen, and therefore indicate the necessity of immediate intervention. Of course, the additional evidence of shock —collapse, rapid pulse, etc.—are also signs which would further aid and fortify a diagnosis. Sometimes a previous knowledge of the pathological conditions, such as a large malarial or leucemic spleen, is important in leading to a diagnosis, when a patient from a slight fall or blow over the splenic region shows evidence of an intraabdominal hemorrhage. Uncertainty as to the seat of the internal hemorrhage demands a median incision above the umbilicus and through this opening an effort should be made to discover by sight or finger the source of the hemorrhage.

As all the conditions with which it is likely to be confused demand operation almost as imperatively as does a rupture of the spleen, there is nothing lost by this incision. Convinced by the procedure that the bleeding arises from a lesion in the spleen, this median incision is not ample or convenient enough for further operative technic, and therefore it is better to augment this vertical incision by a horizontal cut from the upper, and generally parallel to the lower, costal margin towards the left. Retraction of this flap will give ample space for removal of the spleen should it be found necessary. At times even this flap will not suffice to bring down the upper pole of the spleen especially in cases where the dome of the diaphragm is unusually high, particularly when dealing with hemorrhage from large pathological spleens. When such difficulties present themselves it has been suggested to sever the cartilagenous ends of the ribs. This latter procedure will then give ample room and facilitates the removal of soft and friable spleens that are badly ruptured, and which tear and bleed so readily with the least manipulation. On the other hand, if in our preoperative diagnosis we are reasonably sure that the spleen is the affected organ, a better incision would be a vertical one at the outer border of the left rectus, commencing at the border of the costal cartilage, and, if the diagnosis is confirmed when the abdomen is opened, continuing from its upper end outward to the left across the thorax parallel with the borders of the ribs; then retract the flap, and should it be found necessary incise the cartilages. This latter incision gives a better exposure of the entire spleen and permits of an earlier approach for extirpation.

It is conceded that no matter how difficult it may seem to remove the spleen, or how formidable the hemorrhage appears, the safest procedure, if the spleen is found torn or ruptured, is to extirpate it. There is no alternative if the spleen presents a deep tear in one or more places and is bleeding actively. If the opening is sufficiently ample, the spleen not very hypertrophic and not very adherent, splenectomy will not be very difficult. When the abdomen is opened, the belly must be quickly emptied of the extravasated blood and the pedicle of the spleen immediately sought and grasped with the fingers; this offers a provisional ligature and prevents for the time being further bleeding until pedicle clamps can be applied. The spleen, after clamping the gastrosplenic ligament, the lienophrenic and lienorenal folds and separating other adhesions which may be encountered, is then delivered from the abdominal cavity, and its fanshaped pedicle cut closely to its hilus distal to the clamps. The stump is then ligated and, if necessary, its vessels individually tied. Instead of first applying clamps, a ligature with a ligature carrier may be passed through the gastrosplenic omentum and the vessels thus secured.

In those cases where it is found impossible on account of firm adhesions, and where the slightest attempt to separate these adhesions increases the hemorrhages from the spleen, or the condition of the patient is such that further operative procedure jeopardizes his life, tamponade is our *dernier résort.*

Should there be only a small and superficial rent which is easily reached, one may attempt to suture it with a blunt needle such as is used in suturing wounds of the liver, and thus may be able to stop the hemorrhage; however, on account of the friability of the spleen, favorable results are doubtful, and a happy outcome cannot always be expected.

When confronted with an abdomen full of blood, the result of a ruptured and actively bleeding spleen, one meets a situation that is most appalling. To one unacquainted with the technic of a sometimes very formidable operation, the situation is indeed dramatic, for we are dealing with one of the most serious catastrophes that can befall a human being, because the hemorrhage is sudden, in many instances very rapid and so severe that shock is overwhelming, and unless immediate operation is instituted, and one is prepared to cope with the emergencies which may be met, it quickly terminates in a fatal issue.

35 EAST SIXTY-FIRST STREET.

Atresia of the Anus, Rectum and Esophagus

By JOSEPH H. MARCUS, M.D.,
Atlantic City.

According to Von Reuss, of Vienna, the following malformations occur in the region of the hind gut:

Atresia ani.—The anal membrane is closed by a membrane, the skin being either drawn tight over the anus, or in its place there is a shallow dimple or small fold above which the hind gut terminates in a kind of *cul de sac.*

Atresia recti.—The rectum is partially or completely replaced by a solid cord, the signal terminating at the sacrum or still higher up by an ampulla. In mild cases the atresia may be confined to a short band of tissue. With the pure form of atresia recti an external anus is present, but above the latter there is an obstruction.

Abnormal openings and communications.—In these malformations the rectum does not terminate at the normal place, but in the region of the urinary passages or the genitals, e. g., atresia ani vesicalis, atresia ani urethralis, atresia ani vaginalis, and atresia ani vestibularis. In the malformations mentioned above, in addition to the abnormal communications, there may be a normal orifice of the rectum. These malformations would then constitute fistulæ.

Atresia of the anus is obviously easy of diagnosis. The symptoms of complete atresia of the rectum are those of intestinal obstruction—complete constipation, vomiting, meteorism, visible peristalsis, etc. With a little observation it is comparatively easy to form a diagnosis. In a normal anal opening it is easy to palpate the blind end by digital examination of the rectum. The diagnostic difficulties are experienced if the atresia is very high up; examination with a bougie is at times a deceptive procedure. Abnormal communications and orifices may be recognized by the appearance of meconium or feces in the urethra or vagina, or in some part of the peritoneum, but the fact must not be overlooked that admixture of feces with the contents of the bladder cannot be found in every portion of the urine. The earliest possible recognition of atresia in the region of the hind gut is of the utmost importance, as in the majority of cases an immediate operation is the only means of saving the infant. If the sequelæ of intestinal obstruction occurs the prognosis is much worse. Von Reuss states further that it is only permissible to wait in atresia vestibularis and under certain circumstances in atresia vaginalis. We in the United States are accustomed to divide this type of malformation into three classes: 1, Complete closure of the anus with an entirely normal intestine above; 2, anus closed and in addition the rectum above it exhibiting atresia for a varied extent; 3, anus and part of the rectum immediately above normal but separated by a membrane from the patulous rectum farther up; the layer between the external integument and the blind rectum may attain considerable thickness.

Atresia of esophagus.—All authors agree that the most common congenital malformation of the esophagus is a combination of obliteration through more or less of its extent with tracheoesophageal fistula. Foreign contributors, according to Von Reuss, have reported over one hundred cases of atresia of the esophagus. In this country Griffith and Lavenson have found seventeen published cases since 1920. Von Reuss says: In a large number of cases there exists a communication with the trachea besides the occlusion of the esophagus. In other cases communication with the trachea is absent, there being instead a more or less long and solid central portion situated in the course of the esophagus. Occasionally the obliteration is so extensive that the esophagus appears to be altogether lacking; at other times there is only a thin membranelike septum (Marsh). Most rare is a connection of both esophageal segments with the trachea. Atresia of the esophagus is generally found in otherwise well developed infants whose external appearance immediately after birth presents nothing to attract attention. The characteristic symptoms appear only with the first efforts at taking nourishment. Swallowing is interfered with; after a few successive rapid swallowing movements the infant emits gurgling sounds as the fluid in the *cul de sac* gets into the trachea. Violent attacks of coughing and vomiting occur with threatening asphyxia. As a rule the children suck voraciously. As long as meconium is present in the intestinal canal, stools are passed by the infant, thus exhibiting nothing remarkable in this respect. As soon as the meconium is evacuated, either complete constipation follows, or there are, at most, scanty stools consisting of intestinal secretion. As a rule these infants die from inanition between their third and seventh day, exceptionally not until the second week; unavoidable pulmonary complications occur from aspiration of milk.

Similar symptoms may be found with cleft palate. There also may exist an esophagotracheal fistula with an otherwise normal esophagus and trachae; with the assistance of a stomach tube the diagnosis can be immediately established.

Case I.—P. S., male infant, was first seen on the day of his birth at the Atlantic County Hospital for the Insane. He was well developed and well nourished, weighing eight and a quarter pounds, and upon examination appeared perfectly normal, with the exception of atresia of the anus. Nothing had been given by mouth so there was no obtainable history of vomiting or regurgitation. Dr. H. C. Monroe, the superintendent, kindly volunteered the following family history. The child's mother, L. S., an Italian woman, married, thirty-nine years of age, was admitted to the hospital on January 2, 1919. Her husband was living and well, and there were three children, living and well. There had been no miscarriages or stillbirths; the youngest child was five years old and the oldest was twelve. Otherwise the family history was negative. There was no history of insanity in the family as far as could be ascertained. Physical examination was negative. The patient suddenly became insane in 1918, becoming violent and destructive; would wander away from home and refuse to go to bed at night. She was brought to the hospital on January 2, 1919, and upon admission spoke only Italian, incoherently; even an interpreter was unable to understand her. Was not orientated as to time or place. She refused to eat or to go to bed at night, but remained sitting beside the bed. Was always worried and tried to express a great desire to go home. She was paroled on October 2, 1921, and returned October 4, 1921. From this time on the patient was never troublesome, never expressed a desire to go home, and showed a distinct dislike for her husband. It was soon discovered that she was pregnant and on June 19, 1922, a male child was born; period of gestation, 260 days. Examination of baby showed atresia ani.

The baby was taken immediately to the Atlantic City Hospital and operated upon for atresia ani on the evening of the same day by Dr. David B. Allman. No anesthesia was used. An incision was made from the anus in the direction of the coccyx, the rectum then sewed to the anus and incised; a large amount of meconium was expelled and a catheter was inserted. The atresia found was of the second type mentioned by Griffith and Lavenson, in which the anus was closed and in addition the rectum exhibited atresia to some extent. After operation the baby was fed with a five per cent. lactose solution in sterile water. This food was retained for a few minutes when it was vomited; after a few feedings of lactose solution with the same result breast milk was obtained and fed with similar results. This attempted feeding lasted for twenty-four hours and suspecting an obstruction or atresia in the esophagus or stomach I passed a soft rubber catheter into the esophagus. Five inches from the lips an obstruction was met with, and being unable to pass the catheter further down into the stomach a hard silk fibre catheter was used with the same result, a similar point of obstruction being encountered. The presence of atresia of the anus and rectum, the vomiting and the unsuccessful attempts to pass the catheter into the stomach pointed to an obstruction in the esophagus, and judging from the usual condition in these cases, there was presumably an obliteration of the esophagus in the lower portion. Operative procedure was decided upon. The patient was anesthetized and before the abdominal incision was made a catheter was introduced into the esophagus, but encountered the same obstruction. An abdominal incision was made and the stomach exposed, which was found to be normal in size and appearance, and no tumor or thickening was felt at the pylorus. An incision was made through the anterior surface of the stomach, and no trace of food being found therein, Dr. Allman passed a catheter through the incision attempting to pass through the cardiac orifice, but met an obstruction. A tube was inserted into the opening to the stomach and sutured and 150 c. c. of normal saline solution was introduced into the peritoneal cavity. Rectal feeding and salt solution were given which only postponed the fatal issue which occurred three days later. The atresia of the esophagus commenced at a point approximately one and a half inches from the cardiac end of the esophagus.

Editorial Articles

PROHIBITION

The Volstead Act is a good thing. The Volstead Act is a bad thing. It has brought better health and larger bank accounts. It has increased drunkenness and crime. One can get any statement and any set of figures he chooses on this subject, provided he goes to the right source. Truth about the matter seems certainly most Einsteinian. There has been no prohibition of prejudice from habit and custom, and no abolition of financial and political bias.

The word abolition reminds us that there is an amendment to the constitution aimed at bringing about prohibition of slavery, but slavery exists on a large scale as it did before this amendment was passed. Not negro slavery, it is true, but slavery of men of all colors in industry, a slavery which, through the struggles of labor organization, we are gradually getting rid of as we outgrow slowly our inborn appetite to exploit others for our own gain.

The prohibition act has rid us of the curse of saloons, just as that other amendment rid us of the curse of negro slavery, but we are not at all rid of alcohol nor of its private consumption. The act has abolished the chief source and emblem of intemperance, and the amount of alcohol consumed must be greatly decreased. There is no running from one corner saloon to the other three and no treating until the week's earnings are consumed.

There has been much propaganda based on the assumption that alcoholic drinks now sold are of a more dangerous quality, but we do not know of a time when it was not commented that the alcoholic drinks sold in saloons to the average man were of the socalled fusel oil and rot gut variety. The thirsty are, however, now made aware of the bad quality of the stuff they may buy from the bootlegger, and this has added some effectiveness to the prohibition law and reduced the amount of alcohol consumed.

For some decades previous to the passage of the Volstead Act there had been a decided decline in intemperance, especially among workmen of certain industries in which alcoholism was notorious. Just why, we do not know, though, doubtless, better wages, better living conditions, and other sources of pleasure had much to do with this. The change was noted by the larger visioned men in those industries, and the decline in mortality, especially from tuberculosis, which accompanied this decrease in intemperance, would be explained both by the actuary and the workman himself on no other ground than by a relationship between the two. This tendency to temperance continues, even if it may have had a slight setback by the feeling of antagonism to the prohibition law as it stands. The tendency to temperance continues, but total abstinence is quite another matter and as yet is so far in the future for a large mass of the population that it cannot be enforced, and a law that cannot be enforced to a fairly high degree is worse than no law. No one wants to go back to the socalled good old days of the bar room and saloon, but no one should want a law which is so inclusive as to be out of harmony with the natural appetitive law of human conduct as it exists at the present time.

THE NOISY OFFICE

The New York Medical Journal on several occasions has pointed out editorially the industrial menace of noise. There is no doubt that while the human organism may become habituated to the din of machinery, that constant exposure to auditory stimuli exercises a deleterious effect upon the nervous system. This is even more pronounced in the case of brain workers who must concentrate to greater degree upon their work than the manual laborer. Ideation is slower and the finished product less accurate in an environment of gnashing adding machines, pealing telephone bells and rattling typewriters. Leather lunged Stentors rend the air with telephone conversations and, the pest of pests, the gabby officemate reduces the output of exact work. These interruptions make it necessary for the mind to switch on and off the target and, since the inertia of rest must be broken each time the continuity of effort is checked, the load which the human machine carries is thereby greatly increased. Is it any wonder that office workers as a class are more likely to have a subnormal state of nervous health and a shorter life span than does the group which labors in relatively quiet surroundings, when the greater strain to which they are subjected is considered? If it is necessary that the directing heads of large businesses be officed in sound proof, silent rooms, how much more is it requisite that the stenographer, the clerk or the proofreader have the benefit of a hushed office in which every sound is cut down to the irreducible minimum.

Anyone who has traveled widely must have been struck with the fact that the lower the civilization of a people, the more they indulge in purposeless noise. It is true that they have no pneumatic riveters, roaring airplanes or screeching steam whistles, but the amount of entirely useless chattering, pounding and vociferation which can go on in a native village is almost unbelievable. Their mental life is on a very low and narrow plane and concentrated thought, such as is required for creative effort, of rare occurrence. It is only when man reaches the higher levels of civilization that a definite effort is made to eliminate noise. Measured by this standard many of our offices are still pretty far down in the development scale.

It is well worth the effort of those who administer offices to hang out the SILENCE sign and to undertake careful studies with the view of reducing the tumult in which many people are obliged to work. It is surprising how many sounds may be gotten rid of by proper office discipline, how easily a quiet telephone voice, far more effective than trumpet tongued bellowings, may be cultivated, how much peace may be engendered by rubber castors, quiet typewriters and padded adding machines. Every sound eliminated increases the general efficiency of the office force and best of all there will be a coordinate improvement in its mental health.

PREVENTIVE TEACHING AND PRACTICE

The teaching and practice of medicine and surgery, of course, especially of medicine, seem to be pointing more and more in the direction of prevention. Sanitary measures efficiently carried out, aided in some instances by other protective methods, have resulted in the virtual abolition of the epidemic diseases which used to take heavy toll of the population in civilized countries formerly. But environment is still responsible in industrial countries for a great deal of avoidable sickness and for many deaths which might be prevented. In the big cities of this country, there are large slum areas in which people live under conditions which are not only bad for the dwellers themselves but are a menace to the entire community.

It appears to be often forgotten that there are certain diseases which are engendered and fostered in the tenement districts of large centres of population which can be easily transmitted to persons living outside these districts, and that therefore it is advisable for the sake of the whole population that such pest spots and sources of danger should be eradicated. The president of the British Medical Association for this year, who, by the way, is a surgeon, devoted his presidential address to a consideration of the effects of environment upon health and urged eloquently that from the point of view of economy, the question of dollars and cents sometimes moves hearts when other pleas fail. It would be to advantage of all concerned, even of the taxpayers, if dirty, dark, unhealthy houses were cleared away and in their place there were erected, light, airy, sanitary and hygienic dwellings.

The annual report of the London Metropolitan Asylums Board which has just been issued adds weight to the above argument. It reveals the facts that in the year ending May 31st last a sum of $11,756,840 was spent on the treatment of fevers, smallpox, mental deficiency and tuberculosis. Fevers and smallpox accounted for more than half of this outlay, and it is pointed out that in the case of smallpox most of, if not all, this outlay might have been prevented if vaccination had been carried out as it should have been. Vaccination in Great Britain has fallen largely into disrepute, because any persons who wish can evade it for themselves and family by claiming exemption as conscientious objectors.

This too emphasizes what was said previously in this editorial that by neglecting preventive measures which have been proved effective, disease may be and often is spread far and wide and among the innocent and careful. For example, the citizens of London have had to pay for the negligence of some of their number in the matter of vaccination and the inhabitants of other cities may well be invited to ponder over and realize this fact. The situation with regard to the other fevers is different.

The cause or means of transmission of scarlet fever is not known, nor is the cause of measles. These diseases together with diphtheria are responsible for the greater part of the expenditure in London. These diseases fluctuate in their occurrence or recurrence. Sometimes they are quiescent and sometimes they rage. Such fluctuations are little understood but the view that this increase of infectivity is fortuitous is no longer held. No doubt some laws of a definite nature are in operation. Epidemiologists are grappling with this phase of the question at the present time and it is to be hoped that ere long the obscure points will be cleared up when it will be possible to anticipate and avert the disastrous sequels. Experiments in this direction are now being carried on here and in Great Britain and it is a branch of preventive research of the utmost importance.

To return, however, to the matter of disease and environment, there are two diseases which are influenced profoundly by environment, tuberculosis and rickets. Where there is plenty of light and fresh air, both tuberculosis and rickets are rarely met with. These maladies are more affected by environment than any disease, although rickets is probably as much affected by diet as by environment. Yet by the tearing down and clearing away of tenement districts, particularly in New York, and by building houses well lighted, well ventilated and hygienic in every respect, a longer step would be taken towards eradicating tuberculosis and rickets than any possible to be taken.

It is now a truism that public sanitary measures on a large scale have almost exterminated the big epidemics in civilized countries and the object of preventive medicine is now by providing good houses and by education in domestic hygiene to prevent tuberculosis and rickets, the two most crippling diseases known, one of which is the most deadly of civilization, from originating or, at any rate, from developing, as well as to prevent many diseases which are initiated and flourish in dark, dirty and unhealthy environment. Light is the greatest enemy of most diseases and where there is light there is generally health. Diet plays a leading rôle in the production and maintenance of good health and is therefore an essential link of the chain of health. The food eaten by the American people is generally speaking of good quality and generous perhaps, usually too generous in quantity. However, too much pappy predigested food and too much canned food of every description is eaten. Preventive surgery also is forging ahead but the subject cannot be dealt with in an editorial and it must suffice to say that early diagnosis and prompt and skilful surgical measures, as in the treatment of cancer, will often nip in the bud what otherwise might have developed into a serious or fatal disease. The prevention of disease is the truest economy and consequently, however much the primary cost may be, the clearing away of slums is the truest economy. Money properly expended in the prevention of disease is always money well spent and will repay an incalculable amount of interest on the original outlay.

EATING TOO MUCH

A large number of people have dug their graves with their teeth and many are still digging their graves in this manner. Even children who can, of course, consume much more proportionately than adults and flourish, frequently eat a great deal more food than is good for them. A mother is inclined to plume herself on the fact that her infant is continually or almost continually taking nourishment and is surprised that it is peevish and does not seem to make progress. Dr. Eric Pritchard is one of those who have preached in and out of season that infants are often stuffed with food to their lasting detriment by their mothers or by those who have charge of them. While much is heard and written concerning deficiency diseases, and rightly too, little is heard of the diseases consequent on or aggravated by overeating, among both children and adults. There are agents without which we cannot live which at the same time may kill in excess.

A well balanced diet in sufficiency is needful for health but such a diet taken in excess during a prolonged period may easily be highly injurious and in time kill. In hot weather and so far as infants and young children are concerned this is especially the case, and in those fed artificially the fat in the milk may be reduced with benefit. We cannot live without some sugar in the blood, but too much constitutes disease, and the suggestion has been made that diabetes, owing to the system being unable to produce insulin for itself, is brought about by excessive activity, whereby the particular cells in the isles of Langerhans in the pancreas, whose function it is to supply insulin in proportion to the demands made upon them by the diet become exhausted, or, at any rate, impaired so that they cannot provide insulin in adequate amounts.

All diabetic individuals do not necessarily consume to excess starchy and sugary foods; in the chronic diseases each person has probably a predisposition to one or other disease, but the contraction of diabetes does suggest the results of excess in relation to the particular capacity of the cells of the islands of Langerhans of the person afflicted. Thus diabetes is more prevalent among the rich than the poor and, to a certain extent, may be termed a dietetic disease.

In a similar way many of the chronic diseases may be termed dietetic diseases, in the sense of overeating. By continually overstraining the digestive organs by eating unsuitable food to excess, alimentary toxemia is produced, which directly or indirectly causes or intensifies various diseases. That dietary excess is responsible for many diseases and conditions of ill health seems to have been plainly proved by the experience of the war. In all countries and especially in Germany and Austria there was and is in these latter countries, a marked reduction in certain forms of disease associated as to cause with overeating. Diabetes, renal disease, and arterial degeneration have been reduced among the formerly prosperous selfindulgent inhabitants of Germany and Austria, although it is true that the lean diet has increased the prevalence of rickets and tuberculosis in childhood. The increase of cancer among civilized people and particularly among prosperous high living people, gives one to think furiously and to help the belief that after all cancer is a disease of civilization.

The state of affairs with regard to cancer in this country—it is increasing—and the death rate from it tends to suggest, to put it mildly, that cancer is a disease of civilization, that is a disease chiefly affecting a well to do people who eat generously, perhaps too generously. This is a prosperous country, a sanitary country and a clean country, and one in which the general standard of living both as regards housing and food is the highest of the world. And yet the cancer death rate is very high and rising rapidly. As said before, the standard of living regarded from every point of view is extremely satisfactory, and with the exception of a perhaps too liberal diet on the part of the population at large

There absolutely seems to be no reason why malignant disease should be so prevalent and deadly. Is overeating the physiological sin of the citizens of the United States, and is cancer initiated or developed or both by errors of diet in quality and particularly in quantity in those who are predisposed to the disease? The prevalence of cancer in prosperous countries in which the people eat largely is so suggestive that the problem should be closely studied from the viewpoint of civilized life and particularly from the point of view of diet. Eating to excess may be the cause of more disease than is imagined and in suitable food eaten with discretion may be found the master key of preventive medicine.

TROPICAL DISEASE RESEARCH

Research in tropical diseases has developed and is proceeding apace. Now that the uninhabited spaces of the earth are becoming fewer, and the industrial countries are becoming more and more over populated, tropical lands are being looked to as havens for a part, at least, of the superfluous white race populations. Indeed except for their unhealthiness, so far as the white man is concerned, the lands of the torrid zone present many attractive features to settlers of the Causasian race. They are fruitful, generally speaking, when the land is cleared, the soil only needs to be tickled with a hoe and it will laugh with a harvest, but as said before the tropics not only tend to undermine the health of white people but are infested with diseases to which these are peculiarly susceptible and which are much more deadly to them than to the natives.

Doubtless the skin pigment has much to do with the susceptibility and comparative immunity, and it may be true as is thought by some that the white man can never be so immune to the climate and diseases of the tropics as the black man. On the other hand, by taking due precautions, the fair skin immigrant is able to protect himself against the climate, and if it were the climate alone he had to fight, this would not prove an insuperable barrier to a fairly healthy and comfortable sojourn in the tropics. It is certain diseases of the tropics which are so destructive to the life and health of the white man and, to a lesser extent, to those of the black man.

If some diseases were absent life in the tropics would be, for all, divested of many of its terrors. Already the results of tropical research have been so successful as to lead to the hope that if such research is pursued persistently, patiently and under the most favorable auspices that the most menacing tropical diseases will be robbed of their sting, if not wiped out altogether.

A beginning in this direction has been made in the instance of malaria, on the whole the most injurious disease to health ever known. Its mode of transmission to man has been discovered and with it the most effective methods of preventing it and perhaps, in time, of eradicating it from the face of the earth. The discovery is the greatest triumph of tropical research and perhaps of all medical research. It has opened up lands before closed to human beings and has rendered possible important works in tropical regions which before the discovery had been impossible. Witness the Panama Canal.

The discovery pointed the way to discoveries of a like nature, for example that of the transmission to man of yellow fever by a mosquito, the result of the selfsacrificing work of the American Yellow Fever Commission appointed in 1900, consisting of Reed, Carroll, Lazear and Agramonte. It will be futile to attempt to point out in the course of an editorial, the discoveries made with regard to parasitic and insect-borne diseases. It must suffice to say that the importance of the study of parasites in relation to human disease to mankind in every part of the world, even in those parts free or comparatively free from parasites, is becoming daily more obvious.

Such diseases as kala-azar, sleeping sickness or plague have more than an academic interest for civilized people and especially for Americans, irrespective of the fact emphasized in a former part of this editorial, that their presence and prevalence largely aid in deterring white men from living in and making full use of the riches of the tropics for the benefit of mankind at large. The importance of parasitic diseases is of much wider scope on account of the modern facilities for communication and owing to the extent of foreign immigration. These conditions have brought distant regions together in such a way that things which affect one part may easily affect another remote part. And further this country is especially prone to the importation of tropical diseases because of its large immigration from tropical lands.

It has been stated in a recent edition of Asa C. Chandler's work on animal parasites and human disease that in the port of San Francisco alone over fifty per cent. of 6,428 Orientals whose feces were examined in the course of a little over two years were infected with hookworms and according to Dr. Billings, U. S. Immigration Service, in 1911 about ninety per cent. of all Hindus arriving were found to be infected with hookworms. Therefore it is plain that the possibility or probability of other diseases becoming established in places not before troubled by them is a subject of vital importance to any community or nation, and for the reasons stated to this country in particular. It may be remarked that some of these diseases have become established already in places which were formerly free. However there is no need to elaborate the point that tropical diseases affect and are a matter of concern to white people living in civilized countries and that tropical research consequently should be encouraged in every possible way. Unfortunately this has not been the case, and workers in tropical research, as a rule, have had to contend with difficulties of every kind, not the least of which has been and is the lack of funds.

The great object lesson of tropical research is Ronald Ross's epoch making discovery that malaria is transmitted to human beings by the bite of the anopheline mosquito. It has been proposed recently in Great Britain that the twenty-fifth anniversary of this discovery should be marked by the erection in London of some fitting monument in commemoration of his achievement. There is in process of organization the nucleus of an institute which it is suggested should be called the Ronald Ross Clinic for Tropical Diseases and Hygiene, in which it is proposed that laboratory research and clinical investigations should be combined as closely as possible in accordance with his teaching. In Great Britain this proposal is earnestly advocated by statesmen, well known men in various branches of endeavor, and by the leading physicians and surgeons, by the Surgeon-General of the Italian Navy, by Dr. P. P. E. Roux, Director of the Pasteur Institute, Paris, by Dr. Richard Strong and Dr. William H. Welch, of Johns Hopkins University, by Surgeon-General Hugh S. Cumming, Public Health Service, U. S. A. Medical science knows no boundaries and he who discovers and shows the way to the prevention of a disease is not so much a national benefactor as a benefactor to all mankind. Ross may be placed in this category; the result of his investigations has been the saving of millions of human lives and much suffering with the promise that the most devastating disease ever known may be done away with. To say that no monument can repay the labors of such a man is to put the situation baldly. But it is right to say that if a monument is to be erected, the one proposed is the most fitting.

SEX EDUCATION

Man passes, in the course of his existence, through two very distinct and very different periods—the asexual life and the sexual. The statement of this fact is trite and its acceptance in theory is unquestioned, but its practice is, or has been, nearly nonexistent. Moreover its lack of application is a source of grave evil to society. The reason for this is that, after man has passed from the first into the second stage of existence, from the asexual to the sexual, he forgets entirely the life he led in the first period, and cannot retroject himself to the mental atmosphere and mental outlook of his prepubertal career.

Before puberty the child has no genital sexual appetites or appetencies. He may be told or may read anything about sex, and, aside from furnishing him with information, it otherwise rolls off his mind like water from a duck's back, for there is no means for its entrance. The young child is, however, like all animals, curious, and he inquires as to his whence and how. If told, at this time, the plain, good and beautiful truth about his coming, he takes it as a matter of course and the information is pigeonholed where it belongs and in its proper order. There is no commotion in his brain or bodily mechanism. The knowledge came when it was wanted and needed. If the knowledge of his origin is withheld or falsified, there is no such mental fulfillment and seeds are laid for trouble because he must then get the truth from bad sources and at a delayed date.

Most parents do not give a truthful statement to the prepubertal child's inquiry and the reason is that, after the development of the sex life, there is, as we have stated, such dominance by sex that the appreciation of one's own age of innocence and of innocent desire for truth is so nearly lost that we are afraid we are going to do some awful damage to the child mind by giving that which, at the time, can by no possibility injure him. This fear of truthfulness is accented also by the source from which the parent usually acquired, too late, the little knowledge he had of his origin.

The whole bugaboo of sex education lies in this loss, by adults, of the attitude of the child mind and their total inability to retroject themselves and to converse in a sane, wholesome, and truthful manner about the most wonderful and beautiful thing in life. When it comes to children beyond the age of puberty the same straightforward truthfulness cannot harm, because the truth is bound to be learned, and the more simple and direct the route the better, and from the wiser sources the better. There really is no bugaboo about sex education except that which we create within our own ill taught, near sighted, tainted, adult mind. Except they become as little children, the parent and the teacher are not likely to enter, with the child, the kingdom of heaven. They are more likely to land in hades.

◆

News Items.

Oral and Plastic Surgeons to Meet.—The third annual meeting of the American Association of Oral and Plastic Surgeons will be held in the Rose Room, Congress Hotel, Chicago, Ill., Monday and Tuesday, October 22d and 23d. An interesting program has been arranged and those interested in this field of surgery are cordially invited to be present.

Post-Graduate Medical School Lectures.—The New York Post-Graduate Medical School has arranged a course of lectures on phases of medical practice of current interest, to which all members of the medical profession in New York and vicinity are invited. The lectures will be given on Friday afternoons at five o'clock. Further notice of the exact dates and subjects of these lectures will be mailed to any physician who will send his name and address to the Dean, New York Post-Graduate School and Hospital, Second Avenue and Twentieth Street, New York.

Southern Medical Association Reunion.—During the meeting of the Southern Medical Association it is hoped that the Alumni of each of the Medical Schools represented will meet together at dinner. The evening of Wednesday, November 14th, has been set apart for that purpose. The Committee desires to know approximately the number of diners to be expected at each of these reunions. Those who expect to attend should therefore notify Tom A. Williams, Chairman Alumni Diners, Southern Medical Association, 1746 K Street, Washington, D. C., by the end of October.

Whooping Cough Mortality Rates.—The relatively high mortality from whooping cough during 1923 to date, following the lowest rate ever recorded in 1922, shows startling contrasts in its mortality incidence when compared with the three other epidemic diseases of childhood—measles, scarlet fever and diphtheria—according to the Metropolitan Life Insurance Company, which has just completed a survey of whooping cough conditions. Whooping cough is the only one of these four diseases which kills more girls than boys; which has a higher death rate among negro children than among white, and which causes more deaths among children in the rural districts than in the cities. In 1917, the whooping cough death rate in the cities of the registration states was 9.4 per 100,000, while that for the rural part of these states was 11.6. Similarly, in 1916 the urban rate was 9.7 and the rural figure 11.4. For 1915 and 1914, the urban figures were 7.9 and 9.2, respectively, while those for the rural areas were 8.6 and 11.4.

Dr. McGrath Back From Cancer Study Abroad.—Dr. John J. McGrath, president of Bellevue and the Allied Hospitals and also a visiting surgeon at these institutions, returned from Germany on the Resolute of the United American Lines after spending two months at clinics in Hamburg, Berlin, Frankfort and Leipzig. Dr. McGrath said that his object was to study the advances accomplished by notable German physicians in the treatment of cancer. It is planned to establish at Bellevue Hospital a department of radio therapy where the most modern methods of treatment of cancer by the x ray and radium will be installed so that sufferers from this disease who apply at Bellevue and the Allied Hospitals, especially those without means to pay for private treatment, may receive the benefit of free treatment. Dr. Arthur S. Unger of 35 West Seventy-fifth Street, who has successfully treated cancer with x ray and radium, accompanied Dr. McGrath on his trip to Germany and returned with him on the Resolute.

Chicago Menaced by Goitre.—It has been conservatively estimated that Chicago has 200,000 persons suffering from preventable goitre, the greatest number of cases occurring in persons between the ages of birth and sixteen years. Seventy-five per cent. of goitre is among school children.

Less Scarlet Fever This Year.—Scarlet fever has shown a marked decrease this year, according to health commissioner's reports. During the past six weeks no deaths had been reported from this disease. Since January 1st to date 6,832 cases have been reported, compared with 8,622 cases during the corresponding period last year.

United Hospital Fund Annual Report.—The administration costs of the fund hospitals for the year were less than seven per cent. of the total income, reports the secretary, Frederick D. Green. This was possible because of the tremendous amount of free service given by physicians and other hospital workers. The largest item of expense is the free care of the sick poor.

Foreign Urology Conventions.—The Sixth Congress of the Spanish Associacion de Urologia will be held at Madrid, Spain, on October 17th. The two main topics for discussion are Hypogastric Cystoscopy, to be presented by Dr. Camina Bilbao, and Indications for Operative Treatment of Calculi in Kidneys and Ureter, to be presented by Dr. Miraved of Madrid. The Twenty-third French Urology Congress will meet at Paris on October 10th. Dr. Andre will preside.

Dr. Mayo Predicts Longer Life Span.—The average life of the human being has been prolonged from twelve to fifteen years as a result of recent advances in medicine and surgery, Dr. Charles H. Mayo of Rochester, Minn., declared at the meeting of the Manitoba branch of the American College of Surgeons. Dr. Mayo predicted progress already made would be surpassed in the years to come. He emphasizes the need of education as the prime requisite in the battle against disease.

Eye Clinics Save Sight of Children.—The Bureau of Child Hygiene operates ten eye clinics which gave 85,000 treatments to 25,000 school children last year, the health department reports. This included 10,000 examinations and treatments at sight conservation clinics to candidates for sight conservation classes. In 1922, 36,000 refractions were performed by ten oculists, who wrote 11,000 prescriptions for glasses. Much refraction on mentally backward and very young children is done by skiascopy or the shadow-test.

New Magazine in Health Field.—In an attractive new dress, in a more compact and readable form, the most recent number of "Venereal Disease Information," a monthly publication issued by the United States Public Health Service at Washington, has just come from the press. This magazine is intended primarily for health officers, physicians, nurses and social workers engaged in venereal disease control activities. The present issue contains several special articles, among which is one on general paresis. The subscription price for this new periodical is fifty cents per year, payable to the Superintendent of Documents, Government Printing Office, Washington, D. C.

VIENNA LETTER.

(From our own correspondent).

Vienna, *June 23, 1923.*

SUBSTITUTION NOT PROSECUTED.

It is not often that the courts are called upon to decide on the merits of a case of substitution of drugs in dispensing prescription, despite the great scarcity of some medicinal and food preparation, and also despite the exorbitant prices which are prevalent in the present unfortunately low exchange value of the depreciated Austrian currency. If, however, such cases occur, luckily enough, very infrequently, the courts are not asked to assess damages for injuries received from such substitution, the public being used to get substitutions from war time.

A case has, however, just been decided in the High Court of Justice of Vienna in which a patient unsuccessfully took action against a drug company for substituting cocaine for novocaine in the dispensing of a prescription. It appears that the patient, who was known by her family physician to be especially susceptible to the influence of cocaine, was ordered by him a proprietary mixture containing one centigram of novocaine to each dose. The druggist not having the mixture ordered, substituted another, containing half a centigram of cocaine to each dose. As a result of taking the medicine, the patient suffered from acute cocaine poisoning, which reacted seriously on her state of health. The judge who heard the case took the extraordinary course of accepting the opinions of the person who dispensed the medicine as those of an expert witness, although he had no scientific or medical training and on his evidence alone decided to dismiss the case stating that there was no evidence of an excessive dose of cocaine having been administered. Had such a case found its way into the court before the war, the druggist would have surely received a different kind of consideration.

THE VALUE OF KOPLIK'S SPOTS IN EARLY DIAGNOSIS OF MEASLES.

In a recent issue of a medical monthly Dr. Narratil says that he had looked for the spots on the buccal mucous membrane, first described by Koplik as preceding by some days the general eruption of measles, and he had found them in twenty-four cases. In one case they preceded the eruption by six hours, in eleven cases by twenty-four hours, in three by thirty-two hours, in four by forty-eight hours, in two by three days, and in two by six days. The spots were generally situated on the mucous membrane of the cheeks opposite the molar teeth, but occasionally also on the lips, beginning as slightly raised, bluish white, circular, sharply defined points, in size less than a pin's head, and surrounded by a narrow red areola. In a few days they generally increase slightly and become more prominent and the areola enlarges and becomes irregular in outline. Their number varied between six and twenty, and the time during which they persisted from two to six days. They were most marked just before or at the time of the general eruption. They were not present in fourteen cases. Since they are never seen in other conditions accompanied by fever, they become of the greatest importance for the early diagnosis of measles. Narratil claims that the buccal eruption in measles was first mentioned by Gerhardt, and that their importance was recognized by Filaton in 1895, a year before their independent discovery by Koplik.

THE HEART IN TUBERCULOSIS.

In the Vienna Medical Society, Dr. Herz, lecturer on diseases of the heart in the University of Vienna, said that since the announcement by Rokitansky, in 1846, of the theory of the supposed antagonism between valvular heart disease and pulmonary tuberculosis, many observers have sought to bring forward clinical evidence in its favor. It is generally believed, that valvular disease affecting the left side of the heart has a more or less retarding influence upon the progress of chronic phthisis, or even that individuals so affected are to some extent exempt from the attacks of the tubercle bacillus. The explanation which has been offered for this antagonism is that a sort of immunity is conferred through the venous stagnation and consequent chronic congestion which is maintained throughout the pulmonary circulation. That this socalled immunity is by no means absolute, nor, indeed, constant, is proved by the fact that the concomitance of the two affections not infrequently occurs. Dr. Herz has found that smallness of the size of the heart, which was at one time thought to be an important predisposing cause of tuberculosis, is generally discovered at the postmortem, as ably described by Dr. G. S. Norris, of Philadelphia; but Dr. Herz considers that this may be equally the result of the generally impoverished condition of all the bodily tissues. On the other hand, patients suffering from pulmonary stenosis are exceedingly prone to contract phthisis, and this is not surprising when it is borne in mind that this particular cardiac lesion is frequently associated with congenital abnormalities which do not improve the general poorly aerated condition of the blood. Actual tuberculosis of the heart itself is decidedly rare, but it has been estimated that some degree of tuberculous endocarditis is met with in something under five per cent. of all cases of phthisis submitted to an autopsy. Degeneration of the cardiac muscle commonly occurs in pulmonary tuberculosis, which probably accounts for the failure of digitalis in many cases.

EARLY DIAGNOSIS IN MENTAL DISEASES.

At the recent meeting of the Vienna Interhospital Medical Association, Dr. T. Gaspari introduced the subject stated above. He defined insanity, according to Burr, as a "prolonged departure from the individual's normal standard of thinking, feeling and acting." A comprehensive definition would include mental defect from whatever cause, and mental perturbation of whatever degree. Any or all of the elemental processes of sensation, perception, ideation, reasoning, judgment, memory, may be impaired in insanity. In his paper, the nature and degree of impairment of these elemental processes and of emotion and volition in different forms of insanity were touched upon. Subjects discussed at greater length were the distinction between confirmed inebriety and true insanity of alcoholic origin; the differential diagnosis of alcoholic pseudoparesis and paretic dementia; certain phases of hysteria, and the diagnostic difficulties pertaining to paranoia and recurrent mania. Neurasthenia was a euphemism often employed to obviate the necessity of plain speaking, or might be used erroneously to explain symptoms in the early stages of an organic malady. The selfdeception on the part of the physician or his inaccuracy in diagnosis led to improper methods of management, and the prescription of travel often made for such patients was deplored and incidentally hospital care for neurasthenic cases was advised.

PREVENTION OF HEART DISEASES.

Dr. Arthur Hasenfeld, lecturer on heart diseases in the University of Budapest, delivered an address on this. He discussed in what manner the principles of prevention could be applied to various heart affections. He regarded the removal of all chronically diseased tonsils (this was first recommended by Dr. R. Babcock, of Chicago,) as of the utmost importance in all persons who had once had an attack of inflammatory rheumatism, whether the heart had been damaged or not. If infection could be prevented, cardiac inflammation could likewise be obviated. This statement applied to affections other than rheumatism. He then mentioned syphilis and gonorrhea, saying that these diseases sometimes attacked the cardiac structures. Pneumonia, chorea, and scarlatina are sometimes accompanied or followed by acute or chronic endocardial mischief, while influenza or diphtheria may attack the myocardium in an inflammatory way, so as seriously to impair its integrity. Until we could prevent such infections, we could not guard against the cardiac structures being attacked.

The author discussed chronic myocardial diseases, the toxic influence of syphilis, alcohol, and chronic lead poisoning, fatty heart, and particularly cardiac overstrain, as it is observed in the young, and sometimes in the middle-aged, and apparently healthy, as the result of excessive physical exertion, and mentioned typical examples of this kind.

MUNICIPAL DENTISTRY IN AUSTRIA.

The Austrian medical papers have often urged that some method of dealing with children's teeth is urgently needed, and that it would be a great advantage if such inspection and treatment could be made available for the working classes generally. They accentuate, that the amount of ill health and digestive trouble attributable to unsound teeth is incalculable, and returns from every source show the evil to be increasing to an extent that can almost be termed alarming. The difficulties that stand in the way are each of interest in the question, and the all important question of expense; certain it is that the latter will never be solved till the former changes considerly. The papers call the attention of those who are disposed to make the matter a practical one, to the German system. Some of the larger towns in this country have both the power and will to appoint municipal dentists, and these officers are already at work for about thirty years.

In Frankfort last year 2,666 children were subjected to dental inspection, with the result that no fewer than 2,912 teeth were found too much decayed to be saved, and were therefore extracted, while 699 were stopped. The plan that is followed is for each teacher himself to take his class to the dentist, who examines the children, one after another, noting on a card the state of the teeth as he finds them. When defects are found the patients are ordered to come up on a Saturday and the extractions and fillings are then performed. Not only is the importance of sound teeth being recognized in Germany, but Roumania—a relatively backward country of the great civilized powers in questions of public health—is also taking the matter up, and nine municipal dental institutes for the supervision of teeth have been set up. These facts, surely, may serve to strengthen the hands of those who would like to see similar advantages conferred to the Austrian school children.

THE RELATION OF ALCOHOLISM TO CRIME.

At a recent meeting of the Society of Medical Practitioners, Dr. Glückstal, medical expert attached to the law courts, reported that of 188 individuals charged with homicide, examined by himself, there were twelve malingerers and eight persons who were wrongly supposed to be the subject of mental defects. Of the remaining 168 criminals only twenty-eight were females. The following conditions of health were noted: one case of pregnancy, with mental derangement; one delusions of persecution; two of morphinomania; three of hysteria; ten cases of delusions of persecution; eleven of various states of mental disorders; fourteen of hysteria or epilepsy; eighteen of various diseases, either supposed or known to have an effect on the brain; sixteen of mental defect; and the rest of alcoholism. Dr. Glückstal emphasized the fact that alcoholics formed more than a third of the total number of persons charged with homicide. He added that an examination of the antecedents of criminals grouped under other headings would show that many of the epileptics and mental defective subjects were the children of alcoholic parents. He also pointed out that acts of extreme violence might be committed, not only by habitual inebriates but also by persons in a state of occasional alcoholic intoxication, in illustration of which he quoted cases.

THE TREATMENT OF NERVOUS BREAKDOWN.

The number of nervous breakdowns consequent upon changed political and economic conditions has been largely increased, and recently the neurological section of the Medical Society of Berlin held a meeting to discuss the treatment of neurasthenia. During the discussion Dr. Fenwald advised the use of psychoanalysis, and the selection of amusements, according to the results of examination. Cards and other indoor games, open air sport, plays, and conversation on subjects which arouse the patient's interest, frequently have a beneficial effect. Dr. Fenwald has found visits to friends or complete change of environment valuable. When treating patients in their own homes, he has often found it unwise to relieve women of light household duties, or restrict men from moderate exercise. Exercise and occupation (in the sense of pastime) have a disciplinary effect on patients, the curative value of which is not at present sufficiently recognized, but which he believes to be of inestimable value. Careful selection of cases is necessary. If women were taught dressmaking and millinery, dairy work, basket weaving, the lighter forms of wood carving, drawing, painting and clay modelling, and if men were taught pipe fitting, pattern making, mechanical drawing, carpentry, modelling, gardening, stenography, typewriting, painting (signs and frescoes); and if both men and women were to have a choice of work—then Dr. Fenwald believes our institutions for the treatment of mental diseases would speedily be transformed.

Book Reviews

CIRCULATION

Modern Aspects of the Circulation in Health and Disease. By Carl J. Wiggers, M.D. Lea & Febiger, 1923.

The appearance of a second edition of Wiggers's monograph will be welcomed by all internists. There is a serious lack in American literature of books conceived and written as is this treatise on the circulation. A well balanced and selected discussion of the physiology of the circulation, both normal and pathological, forms the basic subject matter of the book. The clinical sections are naturally derived from the foregoing physiological presentations. The monograph is divided into three sections. The first section is devoted to the circulation in health; the second section deals with the various instruments and procedures which are available for studying the circulation in man. In the third section the data obtained by experimental investigation of abnormal conditions in the laboratory are corollated with the results derived from the application of instrumental methods at the bedside, and these in turin are related with the simpler clinical signs and symptoms. Several new chapters have been added. Throughout the book Dr. Wiggers has incorporated the results of his own well known investigations on the circulation. The bibliography is well selected and gives evidence of the author's scholarly knowledge of his subject. Special emphasis is placed on the dynamics of the circulation, and electrocardiography is allotted its proper sphere as an important, but by no means the most important method of clinical examination of the heart. In his discussion of the blood pressure in auricular fibrillation the author recommends the use of James and Hart's average systolic pressure although Cohn and Lundsgaard more recently have shown the inaccuracy of this procedure. The book can be studied with profit by every physician wishing to obtain a through understanding of the modern aspects of the circulation in health and disease.

GREEK MEDICINE

Greek Biology and Medicine. By Henry Osborn Taylor. Our Debt to Greece and Rome. Editors, George Depue Hadzsits, Ph.D., University of Pennsylvania; David Moore Robinson, Ph.D., LL.D., The Johns Hopkins University. Marshall Jones Company, Boston, Massachusetts. Pp. xv, 151.

Misery may desire to join company but how much more does the worker happy in his field delight to find the companionship of likeminded men of an age long past. Not the companionship alone but the stimulus of men superior in the genial freedom of mind untrammeled by political or religious bondage and free to exercise their eager intellectual curiosity upon all that Nature presented to them—such were the men of whose work Osborn writes and of whom he has given an appreciative estimate. Their character is visible in their work as is that of their times and their environment. There permitted fearless investigation with flexible formation and discarding of theory which advanced biology and medicine to a point to which the world has been slow to return. For Osborn is able to reveal also, when he reaches the time of Galen, how evidences are arising of tendencies which were to enclose scientific progress through long, dark ages. There is no lack of appreciation of Galen's service nor of the breadth and skill of the man. But there is recognition, too, of the faults that lay in his greatness and of the change of spirit drawing from the outside over the field of investigation. It is a book written for the layman but one through which the trained physician will be glad to replenish his knowledge of the debt owed to the Greek scientists.

FUNCTIONAL CAPACITY

Funktionelles Frauennaturen. Mit 164 Abbildungen nach Naturaufnahmen. F. Bruckmann, A.-G., München, 1923, pp. vii, 324.

This book is a valuable handbook of practical directions by which one may cultivate the functional capacity of the human body. The many illustrations give a very concrete form to the discussion of the means for such cultivation and the reasons why it should take place. But even more do the underlying principles which the author has set forth bring home to the reader the functional possibilities and the control of these which lies within reach of each possessor of a human body. Gymnastic exercise and dancing go only part of the way which Mensendieck points out so much more fully. Indeed they proceed along a misleading way, the former because of the limitation of the movements which leaves them out of touch with the demands of everyday life and also because they are movements directed from without and not the result of thought upon one's own body. Dancing, on its part, is also limited to the unpractical and likely to lead to extremes which have nothing to do with true utilization of the capacities of the body. The same may be said to a degree of sports. The body deserves thoughtful observation directed upon it. This is the keynote of Mensendieck's system. To this end she pleads for untrammeled naked observation of it in its training. Thus its action can be watched and the functional capacities of its various parts be definitely studied. Thus also will its true value be enhanced in the thought of the child as of any one else. This will bring not alone direct results in muscular control but it will build up an ideal to counteract the abuse of the body in frivolities or in the forming of it for the wholesale destruction which the years have just witnessed.

CLINICAL METHODS

Einführung in die physiologisch-klinische Methodik für Studierende der Medizin. Von Dr. Paul Liebesny, Wien. Mit 79 Abbildungen im Text und einer farbigen Tafel. Berlin, Wien: Urban & Schwarzenberg, 1923.

The various physiological methods of physical examination used in the practice of medicine are described. The pathology of disease is entirely omitted, but special emphasis is laid on the theoretical, physiological, and especially, the physical fundamental principles of the methods employed. This little book is intended to serve the medical student or practitioner the purpose of brushing up on the subject before entering upon clinical instruction. It includes the examination of the blood and its circulation, the heart and lungs, digestion, urinalysis, electricity and the electrical apparatus used in medicine, various physiological demonstrations on the frog and the tests used in examination of the nervous system, the auditory apparatus and the eye. It contains much that is not found in the ordinary textbook on clinical medicine.

Medicoliterary Notes.

The *Popular Science Monthly* for September is a number of unusual interest. Among articles well worth reading are a few that will be of particular interest to readers of the JOURNAL. These are: The Story of Insulin—A Miracle of Science, by Donald Harris, who outlines the use of the drug in medicine and describes how it was discovered by an unknown young laboratory assistant, Dr. Frederick G. Banting; Proofs of Evolution, by Dr. E. E. Free; and The Power of Autosuggestion, by Dr. James J. Walsh.

* * *

Goitre is becoming very prevalent in Austria, according to a medical report from that country. It has been proposed to combat its increase and help in its cure by introducing the Swiss method of administering iodine salt. According to this method, very small quantities of iodine are added in the cooking salt. This was carried out for six months in a certain Swiss village, with the result that the whole population was almost entirely freed from goitre. A variation of the treatment is for the teachers in some of the schools to give iodine tablets daily to the children, or water containing iodine is furnished in schoolrooms, or in some cases the children wear little wooden boxes containing iodine, like charms round their necks. Similar methods have been tried on animals. A certain species of trout is known to have goitre and, by putting small quantities of iodine into the water where they live, the fish have been cured of it.

* * *

Three articles of special interest in *Mental Hygiene* for July are Delinquency and the Exsoldier, by Dr. W. F. Lorenz, director of the Wisconsin Psychiatric Institute; More Community Aspects of Feeblemindedness, by Gordon Hamilton, of the Charity Organization Society; and Community Responsibility in Mental Hygiene, by Dr. Frankwood E. Williams, medical director of the National Committee for Mental Hygiene.

* * *

In his recently published book, *Cures: The Story of the Cures That Fail,* Dr. James J. Walsh lays stress on two facts: 1, That anything will cure a man when he has nothing the matter with him; and 2, that the longer a doctor practises, the shorter grows his list of drugs. One of the most interesting of the fake cures described was the theriac, sometimes called the calendar, because it contained as many ingredients as the month has days. This cure was in vogue for several centuries and was believed in as late as the middle of the nineteenth. Drug stores kept on hand all the time a jugful, which was made up of spoiled prescriptions thrown into the jug, left overs from drugs, powders, etc., and anything else useless that happened to be lying around. Its curative properties were as many and varied as its ingredients, for it was taken from anything one might have, from toothache to black plague, and hundreds of persons were ready to swear to permanent cures from its use.

* * *

The Proceedings of the Ninth Annual Meeting of the International Association of Industrial Accident Boards and Commissions, held in Baltimore in October, 1922, has been issued for distribution by the United States Bureau of Labor Statistics as *Bulletin 333.*

* * *

Dr. Irving Wilson Voorhees, assistant surgeon to the Manhattan Eye, Ear, and Throat Hospital and advisory physician to the Metropolitan and Chicago Opera Companies, is the author of a book published by Macmillan on *Hygiene of the Voice.* It treats of the art of singing from the point of view of the physician rather than that of the singer.

* * *

Another of Macmillan's fall publications will be *The Way Things Happen,* a play by Clemence Dane, which will be produced in New York during the coming winter. Clemence Dane is the author of *The Bill of Divorcement* and *Will Shakespeare.*

* * *

Dr. J. L. Blumenthal, acting director of the New York City Bureau of Child Hygiene, has written a series of interesting articles for the *Monthly Bulletin* of the Department of Health, describing in full the recent work of the Bureau.

* * *

The New York Society for the Relief of the Ruptured and Crippled has recently completed a survey of the city. It was found that New York has in all about thirty-six thousand crippled persons. About fifty per cent. of these are less than sixteen years old, and about sixty-three per cent. became crippled before reaching that age. Nearly one half of the cases discovered by the field canvass are not being treated; about 3,700 cases have been diagnosed but have stopped attending clinics; over fifty per cent. of the cripples are not known to any agency. It was found that there are available enough operative beds and sufficient clinical facilities, but that the number of convalescent and custodial beds is too small. Very few crippled children are attending school.

* * *

During the nineteen months of the World War, the battle casualties of the United States were 48,000. During these nineteen months the accidental fatalities in the United States were 126,000, of which 35,000 were industrial, 91,999 in homes and streets, of which latter 25,000 were children of school age, injured on the highways. The moral is that we should make our streets, homes, and places of work more safe.—*Weekly Bulletin, New York City Department of Health.*

* * *

A translation of *Impulsive Acts,* by William Stekel, is announced as one of the fall publications by Boni & Liveright. *The New Psychology and the Parent,* by Dr. H. Crichton-Miller, published by Seltzer, is now on the market.

Practical Therapeutics

THE USE OF COCAINE IN THE URETHRA*

By James A. Gardner, M. D.,
Buffalo, N. Y.

I have been stimulated to review this subject of local anesthetics because of the repeated questions of patients who ask: "Why are you able to treat me with so much less discomfort than Dr. Blank?" I have always kept in mind that very trite saying of Dr. Robert Taylor that, "if you can pass an instrument with less pain than your neighbor, you get the patient." Nobody wishes to be a hero—many patients procrastinate and postpone their visit to the doctor because of the dread of the treatment.

In these days major operations are performed under local anesthesia to the great satisfaction of the patient as well as with the avoiding of the risk of the general anesthetic. Why then should local anesthesia be spared if the patients can be made more comfortable and if by relaxing them, your work is made easier.

A number of drugs used for local anesthesia are more or less effective when injected subcutaneously. These drugs have also been used for surface anesthesia of mucous membrane, but as shown by Sollman cocaine hydrochlorid is by far the most efficient. Neimann (1) isolated the alkaloid from the cocoa leaves as far back as 1860, but it was Carl Koller, an ophthalmologist, who demonstrated it in local anesthetics in 1884. Since that time cocaine has come into general use as a local anesthetic on mucous membranes as well as used by injection subcutaneously. As with all powerful drugs at first there were more or less accidents and a few fatalities. Mayer (2) injected morphine before or after cocaine in three frogs. The control frogs injected with cocaine alone survived while all of the morphine-cocaine animals died. He accepts this as evidence that morphine enhances the toxic action of cocaine. The custom of injecting morphine before using cocaine is deleterious.

Calcium chlorid on the other hand seems to inhibit the action of cocaine. A small dose of cocaine stimulates the frog's heart while a large dose arrests its action, but calcium chlorid starts it beating again. When calcium was given first, there was no toxic action. Further experience shows that while calcium salts arrests the action of cocaine, potassium salts exaggerate it.

Fabray (3) relates a case in which he injected ten per cent. solution of calcium chlorid dispelling the toxic condition arising in a nurse of nineteen following the injection of seven mg. of morphine and the application of a spray of ten per cent. cocaine-epinephrin mixture to the laryngeal mucosa and the painting of the tonsils and the palatine area with the same mixture in connection with tonsillectomy. The calcium chlorid was given slowly intravenously. After two c. c. had been injected, a marked change for the better set in. The convulsions ceased, the rapid superficial breathing became slow and deep, and the rigid extremities relaxed. At the same time the pulse grew stronger. A total of seven c. c. was injected of the calcium chlorid in seven minutes. Convulsions returned several times but the intervals became longer and the convulsions milder, yielding readily to the administration of camphor.

It was Carl Mayer, of Basel, who first recommended calcium chlorid in cocaine poisoning. Mayer emphasized the need of great caution in order that none of the solution may be injected perivascularly, since severe infiltrations that heal very slowly may arise.

TOXIC SYMPTOMS.

The symptoms from mild and transient toxic action of cocaine are generally overlooked or are ascribed to the patient's nervousness, but absorption of the drug may include vomiting, palpitation, dizziness, and sweating or collapse or even death (4). All drugs of this type kill by simultaneous paralysis of the heart and respiratory centre. The employment of artificial respiration with intravenous injection of epinephrin is indicated so that the body has a chance to eliminate the drug. It is, however, to be remembered that serious intoxication has been seen in men following extremely small doses of local anesthetics suggesting the occasional existence of a marked degree of hypersusceptibility and in such cases, doses which are relatively small as compared with the average dose commonly employed, may actually be several times the minimum, which would be fatal in a particular person, so that even the most effective resuscitation may fail under these circumstances.

RELATIVE EFFICIENCY.

For anesthesia of the mucous membrane the relative efficiency may be readily seen. Alkalinization increases the efficiency from two to four times. The solution of the anesthetic salts may therefore be mixed with an equal solution of 0.5 per cent. sodium bicarbonate without loss of efficiency and with a saving of one half of the anesthetic. The mixture does not keep well and should be freshly made. The addition of epinephrin does not increase efficiency and is probably useless. The addition of the alkali serves no good purpose for infiltration, but markedly increases efficiency for use on a mucous membrane, with the exception of quinine urea which is less. If you have accidents or fatalities, they should be reported, so that there may be a better understanding of the cause of such accidents and also that they may be prevented. There is a section on therapeutic research of the council on pharmacy and chemistry of the A. M. A. who have undertaken a study of the accidents following local anesthetics.

In our office during the past ten years a cocaine solution has been used in the urethra preceding over fifty thousand examinations and treatments. There have been no fatalities or serious toxic symptoms. In 1898 I began using a four per cent. and eight per cent. solution of cocaine before passing instruments. Not having many patients the solution was often weeks old when finally used up. As I read reports of fatalities in the literaure I was only too glad to turn to any substitute which would give satisfaction and at the same time be safe.

---

*Read before the Section in Genitourinary Surgery, New York Academy of Medicine. April 18, 1923.

Some years later Dr. Bransford Lewis suggested alapin. After giving it a trial it was discarded, because it did not give satisfactory anesthesia. Experience proved that freshly made, hot solutions of cocaine were more effective than the same strength in old solution. As the price of the drug increased experimentation showed that a weaker solution would give the required anesthesia. Then with the suggestion of Sollman, that alkalization of the solutions increased its efficiency from two to four times I procured one grain sodium bicarbonate tablets which were dissolved with one and one eighth grain cocaine tablets. These tablets dissolved in thirty minims of water make a four per cent. solution, in two drams of water a one per cent solution, and in a half ounce of water a half of one per cent. solution. An aseptic half ounce syringe has been found to be convenient for administering the solution in the anterior and posterior urethra. One has much better control than when the plunger type is used.

Previous to massage of the prostate a half per cent. solution is all that is necessary to anesthetize the anterior and posterior urethra so that the bladder may be filled. I believe that a half per cent. solution, as I have suggested, will give satisfaction in a great majority of cases. For cystoscopic and endoscopic manipulations as well as the dilatation of tight strictures I find a one per cent. solution gives better results. The solution should be injected slowly and the urethra distended for at least a minute to insure a satisfactory anesthesia. This question may seem only of minor importance, but those who have been patients will fully appreciate it.

504 Electric Building.

A SIMPLE TECHNIC FOR COLLECTING BLOOD FROM VEIN.

By Albert M. Crance, M.D.
Geneva, N. Y.

There are several methods of withdrawing blood from a vein for the Wassermann, or other tests, however the simplest and easiest method is the one usually looked for. If the blood is taken with the syringe method, there are many objections. It necessitates cleansing the syringe immediately, else the blood will clot within it. The syringe should be dry to begin with, or else it may harm the test to be carried out. Constant expense of breakage is also an objection.

The direct method seems the most simple, and the one of choice. It is only a matter of carrying it out

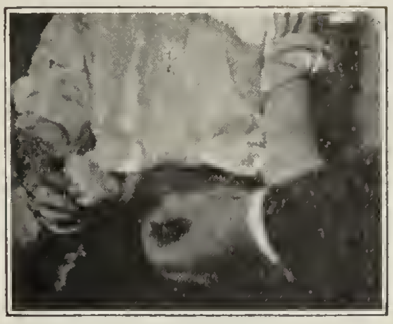

Fig. 1.

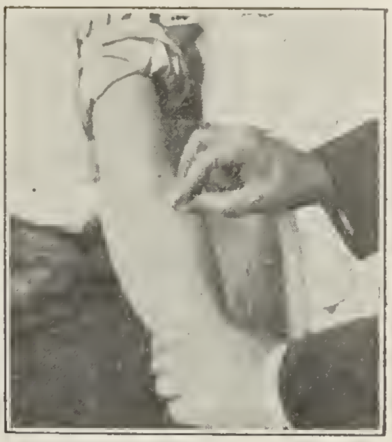

Fig. 2.

Fig. 1.—Step 1.—The patient is placed in a sitting position, either on the table or high stool. He is given a piece of cotton to hold in the right hand. The left sleeve is rolled up.

Fig. 2.—Step 2.—The arm is cleansed as in the usual manner.

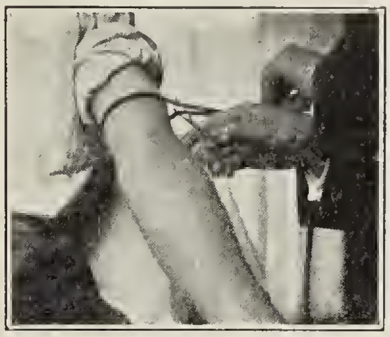

Fig. 3.

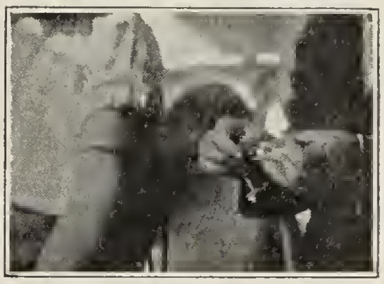

Fig 4.

Fig. 3.—Step 3.—A rubber tubing is drawn once around the arm and tension made with the operator's left hand, while a forceps clamps. In this manner the patient's skin will not be pinched in the tubing.

Fig. 4.—Step 4.—The needle is taken from the sterile wrapper, the needle holder slipped on and adjusted with the setscrew.

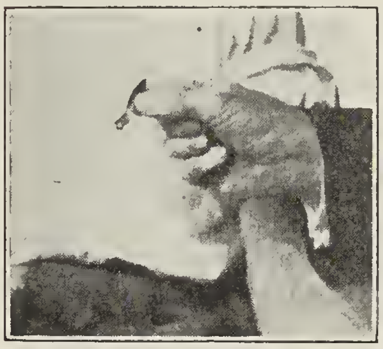

Fig. 5.

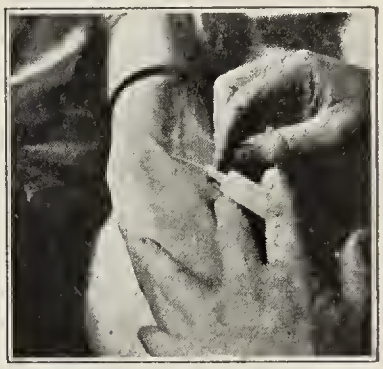

Fig. 6.

Fig. 5.—Illustrating the Swift needle holder and needle ready for use.

Fig. 6.—Step 5.—The tube is held between the index and second fingers of the left hand, the bottom of the tube resting against the thumb. The vein is held firmly in position with the second finger. The needle is held in the right hand, the proximal end is in the tube.

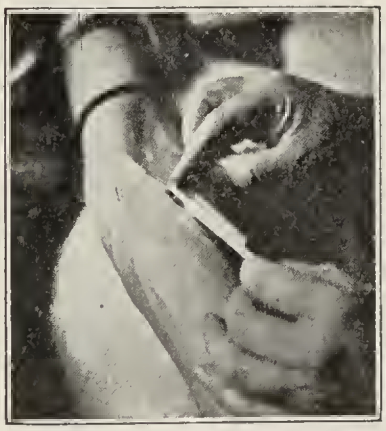

Fig. 7.

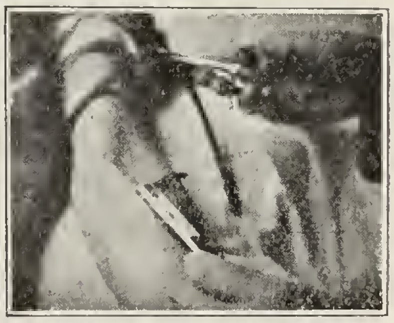

Fig. 8.

Fig. 7.—Step 6.—The needle is inserted into the vein. Illustration shows stream of blood flowing into the tube.

Fig. 8.—Step 7.—When enough blood has been collected, release the forceps, and throw the tubing and forceps aside. The blood will cease flowing.

systematically. The use of a needle holder, such as is shown in the illustrations, makes the procedure much easier, and more satisfactory. The principal things in the method described are the position of the patient, with his arm at his side; placing a piece of cotton in his right hand; the manner in which the tube is held; manner in which it is withdrawn. The method described is simple, quick and very convenient for routine work. With practice, there is no reason why any blood should be spilled on the patient or on the operator.

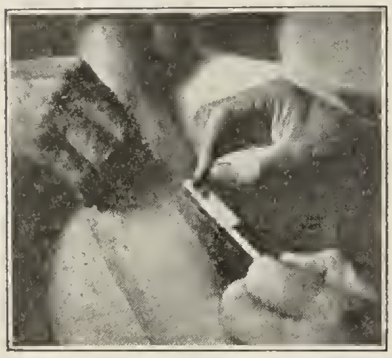

Fig. 9.

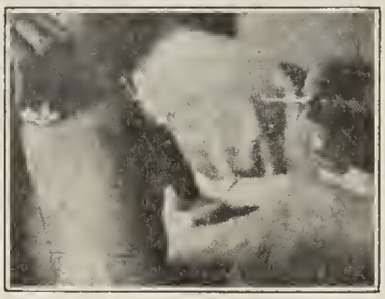

Fig. 10.

Fig 9.—Step 8.—The patient now places the piece of cotton held in his right hand on the area where the needle was inserted, and makes pressure.

Fig. 10.—Step 9.—The needle is withdrawn quickly, leaving the patient pressing with the piece of cotton. He is asked to continue this procedure for about a minute, usually while the operator is corking the tube of blood, and removing the needle from the holder. The photographs illustrate that the procedure should be carried out without losing a bit of blood.

A Modification in the Routine Treatment of Syphilis.—M. Sydney Thomson (*British Journal of Dermatology and Syphilis,* January, 1923) states that the organic compounds of arsenic, even though they do not possess the specificity at one time claimed for them, are nevertheless of undoubted value. The almost miraculously rapid disappearance of signs and symptoms in an early case, consequential on their use, must not be allowed to overshadow the essential importance of continuous mercurial administration. Nor must it be forgotten that the salvarsan group itself is not without danger to the patient. He asserts that the method of administration here described reduces the danger to a minimum without in any way impairing the efficiency of the treatment. The rate of excretion of arsenic must be considered and its accumulation avoided if it is desired to eliminate all possibility of disaster.

Instead of frequent small doses of novarsenobillon, a minimum of three injections of 0.9 gm. is given, the interval between each being at least three weeks. The majority of early cases give a negative Wassermann reaction twenty-one days after the final dose. The blood is tested quantitatively at each injection to observe the effect of the treatment. The minimum of injections is given, even though the negative reaction of the blood appears previous to the completion of the course. The intravenous therapy is continued until a negative reaction is attained. The longer the period between infection and treatment, the greater the difficulty in obtaining a clear test. Few of the early cases require more arsenic than is administered during the first two months of treatment. Mercury is given as soon as a definite diagnosis is made and is continued throughout the whole period of treatment in the form of a tablet consisting of a hydrargyrum cum creta, one grain, three times daily, except for the discontinuance of the treatment because of stomatitis, etc. Once the Wassermann reaction has become negative the patient is given the mercury continuously for at least one year. During this year frequent tests are performed and the patient is kept under careful observation. All treatment is stopped when the reaction has been clearly negative for at least twelve months. The test is then applied every six weeks for a further year. Should this prove continuously negative during the whole period of probation, a lumbar puncture is made and the cerebrospinal fluid is examined. This is subjected to all the tests for syphilis and on its proving satisfactory the patient is discharged as cured. Of course, on suspicious clinical signs must have supervened during these two years of observation.

Flat or Weak Feet in Children.—S. Kleinberg (*Archives of Pediatrics,* January, 1923) mentions the following most frequent and important causes of flat or weak feet in children: 1, static; 2, muscle weakness and anemia; 3, rickets; 4, trauma; 5, infectious diseases; 6, prolonged or exhausting illness; 7, obesity; 8, improper footwear and 9, congenital. There are two types of flat feet—the flaccid and the spastic. The symptoms do not depend upon the severity of the flat feet. Besides pain in the feet, legs, or knees, children may complain of tiring easily, indisposition and irritability. The shoes may be conspicuous evidence of the distortion of the feet during walking, being worn down on the inner side of the heel and sole and showing marked bulging of the shoe over astragalus and inner malleolus. There are two elements in the deformity, valgus abduction of the foot and depression of the longitudinal arch.

Small children with flat feet, even though they are painless, should be treated for the deformity. In a child of two or three years of age, elevating the shoes about quarter of an inch on the inner side of the soles and heels is usually sufficient. The shoe must have a broad toe and low heel. Strapping of the feet and legs to support the varus is helpful. If the raised shoe does not suffice, a model should be made of the feet and a pair of corrective plates should be provided. In a child of three to six years of age, the routine should consist of shoes raised quarter of an inch on the inner side of the sole and heel and corrective foot plates. In a child past six years of age, the treatment should consist of properly constructed shoes raised on the inner side, corrective foot braces and instruction in the proper method of standing and walking; also exercises which involve the use of the plantar, flexor, and adductor muscles of the feet. Properly constructed flat foot braces should be made over corrected models of the individual foot so as to fit properly, should hold the foot in the normal position in relation to the leg and should exert no undue pressure on any part of the foot. These requirements are met perfectly by the Whitman brace. The proper shoe is one that supports the foot and does not constrict any part of the foot or disturb its balance. The shoe should have a moderately low and broad heel, the shank should be narrow and the sole broad and the inner side of the toe from tip to heel should be practically a straight line; the toe should be full and rounded.

Proceedings of Societies

WESTERN SURGICAL ASSOCIATION

Thirty-second Annual Meeting, Held at Minneapolis, Minn., December 8 and 9, 1922.

The President, Dr. Miles F. Porter, of Indianapolis, Ind., in the Chair.

(Concluded from page 252)

Postoperative Ventral Hernia.—Dr. James M. Masson, of Rochester, Minn., stated that the treatment of this condition fell into two subdivisions: preventive and curative. Preoperative medical management of obese patients was essential. They should be put to bed on a restricted diet with increased elimination to reduce weight and to lower blood pressure. Postoperative hernias, not preceded by infection, occurred most often in the low middle line incision. Great care should, therefore, be exercised in closing such incisions, and it was advisable to open the sheath of the rectus on each side and make a closure exactly the same as in the ordinary straight incision. Local nerve blocking, supplemented, if necessary, by nitrous oxide or ether, was the anesthesia of choice.

In cases of small hernia, no preliminary treatment was required, but massive hernias should be reduced as much as possible before operation. The manner of closing wounds would vary with the tissues concerned. Anatomical closure was the procedure of choice, if approximation could be effected without undue tension. In all other cases a plastic overlapping, on the same principle as the Mayo operation for umbilical hernia, was advisable. It was important to remove all possible fat from the surfaces that were to be brought into apposition, and to obliterate any space in which serum or blood might accumulate. Care should be taken not to overlap too much, or undue tension would result. No tags of omentum should escape between the stitches, hemorrhage must be controlled as thoroughly as possible, and fascia should be overlapped wherever possible. All buried suture material should be of catgut, or some absorbable suture material. Twenty-day chromic catgut No. 1 or No. 2 was the suture material of choice.

Preservation of the Facial Nerve During the Complete Removal of the Parotid Gland for Malignant Tumor.—Dr. Alfred W. Adson and Dr. W. O. Ott, of Rochester, Minn., said that in the operation for removing the parotid gland, the inframandibular branch of the seventh nerve was first exposed through an incision which extended from a point three cm. above and posterior to the lower tip of the mastoid and to a point four cm. anterior to the angle of the jaw. The inframandibular branch of the seventh nerve was then traced backward until the temporal and cervical divisions of the seventh nerve were exposed. Then an additional incision was made down from the zygoma and just in front of the ear above the parotid and this incision was connected with the one previously described. The section of the glands should be carried downward in the line of the incision from the zygoma and should be deep enough to expose the mandible and the temporal border of the posterior masseter muscle. The dissection must be kept close to the cartilage of the ear and back of the parotid gland, care being taken not to injure the temporal branch of the facial nerve. By this method the two surgical fields could be connected. After this the temporal and cervical divisions of the facial nerve penetrated only the lower lobe of the parotid for a distance of approximately two cm. after which it lay under the parotid. If this dissection was complete, the skin with the parotid might be elevated, leaving the peripheral branches of the facial muscles undisturbed. The incision was then carried forward sufficiently to elevate all of the parotid, dividing and ligating Stenson's duct. The next step was to lift the seventh nerve and dissect out the deep lobe of the parotid gland behind the mandible and mesial to the seventh nerve. The wound was closed with a subareolar stitch of catgut and with a dermal stitch of horsehair.

Tumor of the Face; Meningocele.—Dr. Herman E. Pearse, of Kansas City, Mo., stated that the patient was a Mexican child, two years of age, who had had a tumor of the face from birth. The patient was given ether anesthesia by catheter into the mouth. Incision was made from the bridge of the nose downward and to the left along the inner edge of the tumor, curving outward beyond the upper lip into the cheek. The tumor was dissected out with some difficulty. It proved to be a cyst filled with clear fluid. The hard base was the cartilage of the nose with a quarter inch of fibroid tissue overlying its upper part. Its dissection laid bare the bones of the upper jaw, the inner angle of the orbit, and the nasal cavity. Within the nose it could not be separated from the bones of the face. The cyst ruptured in attempting to release its wall from the nasal margin. A canal an eighth of an inch in diameter was passed upward to the middle line, where the frontal bones united. It appeared to attach itself to the undersurface of the frontal bone in front of the cribriform plate. No meningeal fluid escaped. At the close of the operation the diagnosis of keratoma seemed most probable, because no discharge of meningeal fluid occurred, but two days later the wound began discharging meningeal fluid, making a diagnosis of meningocele imperative.

Surgical Aspects of Disorders of Digestion.—Dr. Willard D. Haines, of Cincinnati, Ohio, stated that trauma in the absence of infection played little, if any, part in the production of ulcer as demonstrated by the clinician. The fact that ulcers attacked that part of the duodenum extending from the pyloric ring to the point of entrance of the common duct and the pyloric fifth of the stomach, had led to much speculation, concerning the causes for such predilection. The mucosa lining this section of the duodenum was not as well protected from the influence of the acid chyme as it left the stomach as were the duct bearing and terminal segments of the gut, nor was the first part of this viscus as freely supplied with blood as were the second and third divisions.

In dealing with the ulcer, he preferred excision to infolding by suture in conjunction with gastrojejunostomy. One of his earlier papers contained a description of a method of perforating the remaining coats of the stomach wall in operating for gastric ulcer. The method was based upon observation made by the ophthalmologists, that an ulcer of the cornea which perforated always healed. The opening thus made in the crater of the gastric ulcer was closed by tier suture. The procedure served to put the tissue immediately surrounding the ulcer at rest and some benefit seemingly accrued, in that postoperative recovery was in some instances more prompt than when gastrojejunostomy alone was performed. Recently destruction by cautery had been substituted for this method with very satisfactory results.

Cystin Calculi, a Complex Surgical Problem.—Dr. C. E. TENNANT, of Denver, Colo., said that cystin calculi were comparatively rare. Until 1882 only fifty cases of cystinuria had been reported in the literature. Kretschmer, in his comprehensive study of the subject of cystinuria and cystin stones, found reports of but one hundred and seven cases of the stones, including two cases of his own, which occurred in twin boys, nine years of age. Cystinuria tended to run in families, there having been found in twenty-two cases collected by Poland, a group of ten occurring in four families. The disease had also been found in three successive generations.

Cystinuria might be divided into three groups: 1. The low grade form in which the patient could digest cystin administered by mouth, but could not break up that originating within the organism, while neither the oxidation of administered aminoacids nor the oxidation of aminosalts originating within the system was affected. His case was an example of this group. In the second group the patient eliminated cystin formed within the organism. In the third group the severest grade was represented in patients who eliminated administered cystin, as such, although this had not been tested out in any actual case.

The Value of the Röntgen Examination in the Early Diagnosis of Postoperative Ileus.—Dr. JAMES T. CASE, of Battle Creek, Mich., said that the technic which he employed in the röntgen examination was very simple, it being necessary simply to wheel a portable röntgen apparatus to the patient's bedside, slide under him a 14/17 inch film with intensifying screen in the proper film holder and to make an exposure of from two to five seconds. No dressings were removed. No opaque medium needed to be administered. The whole procedure required not more than five minutes. The film was at once developed and it might be studied immediately after being dipped in the fixing solution. The developed film would reveal at once whether there was any gas distention within the abdomen, and if so, whether the distention occurred within the stomach or within the large or small intestine. The small and large bowel might be distinguished by the characteristic outline of the gas areas. The appearance of the gas distended coils of jejunum or ileum were characteristic, lying more or less parallel, the calibre of the gut being increased one and one-half, two and even three inches as measured on the film. A certain amount of postoperative distention of the small intestine was frequently noted where there were no symptoms suggestive of obstruction, but in the serious cases, the degree of distention was at once apparent and suggestive. If doubt still existed as to the fact of the obstruction, a small amount of barium sulphate, say half an ounce, might be administered by mouth in a little water and another film made five or six hours later. Enough barium would reach the small intestine in this time to identify more definitely the small intestines.

Peritoneal Drainage.—Dr. CUTHBERT POWELL, of Denver, Colo., stated that drainage, socalled, of the peritoneal cavity did not remove infection nor did it allow the escape of but a negligible amount of fluid present in the general peritoneal cavity. On the other hand, the presence and pressure of drains undoubtedly militated against the recovery of the patient. Except in definitely localized and walled off abscesses, and possibly in those now fortunately rare late cases of general suppurative peritonitis, when the whole cavity was filled with pus under pressure, drainage was contraindicated. The surgeon's duty had been performed when the focus of infection had been removed and the abdomen closed in as short a time as was consistent with a proper technic, and with a minimum of trauma and exposure of the peritoneum.

Sliding Hernias of the Cecum and Appendix in Children.—Dr. VERNON C. DAVID, of Chicago, stated that while hernias containing cecum and appendix in their sacs were not uncommon, real sliding hernias were rarely seen in children. Coley in 2,200 cases of hernia found the cecum alone in the sac in eighteen, the appendix alone in ten, and the cecum and appendix together in seven. Judd found fourteen sliding hernias in 1,652 cases, and of these six were of the cecum and on the right side. Baumgartner collected 159 cases of sliding hernia from the literature, eighty-five of which were rightsided. Four were left inguinal hernias containing the cecum. The two most discussed factors in the causation of sliding hernia in children were the rotation of the cecum and the descent of the testes during fetal life.

NEW YORK ACADEMY OF MEDICINE

SECTION IN GENITOURINARY SURGERY

Meeting held on November 16, 1922

DR. ABRAHAM HYMAN in the Chair.

The Results Obtained by Various Methods in Tumors of the Bladder.—Dr. HUGH H. YOUNG, of Baltimore, read this paper by invitation. He presented a most interesting series of results, for the most part in statistical form, of his experiences in treating bladder tumors, and made an appeal for the more active use of radium. The paper is published in full in the September 5th issue.

Discussion.—Dr. E. L. KEYES opened the discussion. He stated, in the experimental, developmental stage of treating malignant growths, thanks to fulguration and radium, we were arising from the absolutely hopeless period described by Dr. Young, but had not yet reached any standard method of treatment. Dr. Keyes said it was his own impression, and doubtless that of many others, that we should continue to cure as many cases by fulguration as possible, but that such cases would be for the most part those of papillomata; for carcinomata, x ray or radium, with or without resection, should be used. The really dangerous tumors, the large infiltrating carcinomata, were apparently more curable by resection than the papillary carcinomata. The one place where malignant tumor should not be was at the bladderneck.

Dr. **Edwin Beer** stated that his particular experience was totally at variance with that of Dr. Young and Dr. Keyes, who reported better results in infiltrating carcinoma of the bladder than in papillary carcinoma. He himself had found that infiltrating carcinomata presented the greatest problem in this whole field. It seemed to him that it would be worth while to standardize the treatment of bladder tumors so as not to vary, and he outlined a method of standardization. He believed that, in infiltrating carcinomata, the use of radium would be more relied upon, and the combination of partial removal with implantation of radium, would give better results than a simple operation.

Dr. **B. S. Barringer** favored radium rather than operation in the removal of bladder carcinomas, for, 1, radium destroys cancer cells more easily than normal cells; 2, it produces an obliterating endarteritis which destroys the nutrition of the carcinoma and so destroys the growth itself. Also, he said, there was a large class of tumors and carcinomata which could be destroyed by the intravesical use of radium, either applied on the surface, or by implanting radium seeds in the base of the tumor. In this way, many infiltrated carcinomata could be destroyed without operation. Again, when there was a large tumor that had to be exposed by suprapubic section in order to put the radium in, the operation was a shorter one than the excision of the tumor by operation alone, and there was less disturbance of the kidney. In his opinion, most of the cases who died did so because of failure of the kidney function.

Dr. **Leo Buerger** said it was his custom not to regard any tumor as absolutely benign, but as potentially malignant, for his experience had shown him that in apparently benign papillary growths tumor cells may be found already in the lymphatics at some distance, and these cells may show abnormalities although the pedicle of the tumor, histologically, is nonmalignant. The successful results obtained from the fulguration method, however, had shown that the percentage of manifest malignancy was not so great as many believe. His treatment of primary carcinomata consisted of snaring the tumor, then fulgurating the base. He was not so enthusiastic about the use of radium as the others, especially as regarded surface applications. His method was to introduce radium into the bladder with the aid of the cystoscope, with which it was possible to leave the metal needles in place attached to a thin wire. A form of carcinoma where radium offered great advantage over operation was that type situated near the ureteral orifice or starting in the lower end of the ureter at the lips of the ureter's vesical orifice. These could be made to disappear by the use of the Buerger cystoscope. In recurrence radium was very valuable; in all cases of inoperable carcinoma it should be employed.

Letters to the Editor.

CONCERNING THE ETIOLOGY OF GASTRODUODENAL ULCERS

New York, *August 13, 1923.*

To the Editor:

I have noticed Dr. F. B. Turck's letter in the New York Medical Journal and Medical Record, August 1, 1923, concerning my article on the etiology of gastroduodenal ulcers which had appeared in the June 6, 1923, issue of the same journal. If I misinterpreted Dr. Turck's ideas it may be my fault, or it may be because Dr. Turck has not made them clear enough, but I distinctly remember having read a few years ago in the *Medical Record* an article by Dr. Turck, wherein he stated that he had produced peptic ulcers in dogs by feeding them with Bacillus coli, and he also stated there that the gastric acidity enhanced the development of these microbes. Unfortunately, I cannot now lay my hand on that article.

That I am not alone in thus being mistaken can be seen from an article by A. C. Ivy, Ph.D., in the *Journal A. M. A.*, vol. 75, p. 1539, December 4, 1920, wherein the author states: "Turck reported the occurrence of perforating ulcers of the duodenum and stomach on feeding cultures of Bacillus coli." Nothing else is mentioned besides the Bacillus coli.

I am glad, however, that Turck does not agree with the bacterial theory of this affection. Still, I regret to say, his animal experiments do not explain the peculiarities of these ulcers, such as their rarity in children, their occurrence in hyperchlorhydria or normal chlorhydria and seldom, if ever, in achlorhydria, etc.

I agree entirely with Dr. Turck concerning the great value and importance of animal experimentation. But while serving as a corrective of our notions of human medicine, it must also elucidate, complement, and explain the phenomena of human physiology and pathology, and not be at variance with well established pathological and clinical data in man, otherwise the results of animal experimentation are of greater interest to the veterinarian than to the physician.

I will quote again from the excellent monograph of Welch on ulcer of the stomach (*Pepper's System of Medicine*, Vol. 2, p. 514): "Gastric ulcers have been produced experimentally in animals in a variety of ways, but these experiments have not materially elucidated the pathogenesis of ulcer in man." And I shall add that the latest experiments on animals have not done so either. Now, my theory, which is based on the laboratory study of the urine and stomach contents of patients, explains all the phenomena concerning the disease in question. I have even tried a new treatment with apparently beneficial results, namely, the exhibition of urotropin, which I have found beneficial in phosphaturia in general. But I considered it premature to dwell on treatment, and I did not mention it in my previous article.

Now let others, with more means and facilities at their disposal, do the rest in clinical observation and animal experimentation, if my theory interests them. I am satisfied that I have, so to say, made out a good case in favor of my theory.

E. Palier, M. D.

Abstracts from Current Literature

PEDIATRICS.

Infant Feeding: Facts and Fallacies.—James Burnet (*Archives of Pediatrics,* February, 1923) shows that many fallacies are allowed to creep in the feeding of cow's milk and its preparation. The milk should generally be diluted to reduce the protein. Plain water is the best diluent. Sugar is by no means necessary for every infant and it may cause digestive trouble; there is absolutely no need for milk sugar, which may cause indigestion in some cases. The use of cream is rarely necessary and the author prefers to use a good milk in which there is a proper amount of fat. The author believes in simplicity in infant feeding, with which he has obtained good results.

Rickets.—Eric Pritchard (*Archives of Pediatrics,* February, 1923) believes that all conditions of malnutrition in infants and young children, arising from any cause whatsoever, whether of bad feeding or malhygiene, provided they are severe enough and long enough continued, must inevitably lead to rickets, because all such conditions conduce to the development of an acidosis, and consequently to mineral depletion and calcium impoverishment, which is the fundamental cause of the rickety condition. He shows that all known and recognized etiological factors in rickets are also familiar etiological factors in acidosis; that all the clinical symptoms of rickets, that is, the mineral depletion of the tissues, the excessive calcium output in the emunctories, the muscular debility, the nervous irritability, etc., result from an acidosis which creates a demand for calcium which is far more urgent and vital than the less essential claims of growing bones or other tissues; furthermore, the prophylactic and curative treatments of rickets and acidosis are the same. Finally, it seems fairly obvious that if such utterly different etiological factors as vitamine starvation, carbohydrate excess and improper hygienic conditions can all lead to rickets, there must be some common ground on which they all meet, which can be no other than that particular phase of metabolic failure which results in the incomplete oxidation of the food which serves as the source of bodily energy and which leads to the production of an excess of acid bodies. For this reason and by a process of exclusion he believes that all the various etiological factors of rickets are merely remote or contributory factors.

The Fat Soluble A Vitamine and Rachitis.—C. E. Bloch's experiments (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) indicate that clinical rachitis is not due to a deficiency of fat soluble A vitamine in the organism or in the food. Clinical experience shows that rachitis cannot be a deficiency disease, as it develops not only independently of the amount of the fat soluble A vitamine in the food, but even when all the other necessary substances are present in the food in sufficient amounts. Two clinical observations, however, indicate that rachitis is due to a deficiency of the fat soluble A vitamine: the curative action of codliver oil, which contains much fat soluble A vitamine and that rachitis heals spontaneously during the summer months. Rachitis is not cured by the fat soluble A vitamine in the form that it occurs in milk and codliver oil must contain other substances than the fat soluble A vitamine that are effective. The result in the treatment of rachitis with ultraviolet rays indicates that the sunlight also has a therapeutic value. Nevertheless, the fat soluble A vitamine is a very important element in the diet.

Feeding with Butter-Flour Mixture.—Richard Hamburger (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) asserts that the reserve fat formed as a result of feeding fat has certain advantages over the fat resulting from the feeding of carbohydrates in certain infants. He favors the addition of one hundred grams of a soup containing five grams of butter and five grams of flour. The same dangers as regards tuberculosis lurk in raw butter as in raw milk. This mixture is useful in mixed feeding cases. The contraindications for its use are acute disturbances and atrophy. If the feces show a neutral and alkaline reaction, or even a weakly acid reaction, the fat is well tolerated and the stools will show calcium soap. If the feces are strongly acid in reaction, this mixture may result in increased dyspepsia, as a result of the formation of fatty acids. Slight constipation may also result. The addition of sugar improves the condition; if it does not help, or if diarrhea develops after the use of the butter-flour mixture, the use of fat should be discontinued.

Enuresis in Children.—N. T. Saxl and Peritz M. Kurzweil (*Archives of Pediatrics,* March, 1923) advance the following rules and regulations in all cases of enuresis, which must be carefully observed by the parents and the patient:

1. No coffee, tea, cocoa, or spirituous liquors of any kind. 2. No fluids of any nature four hours before the hour of retiring, with the supper, consisting of solid food at a stated time. 3. A cold friction rub to the chest, sides and lumbar spine is sometimes advised in older children. 4. Elevate the foot of the bed one or two inches from the floor. 5. The patient should sleep on the right side and not on the back and a towel should be tied around the patient with the knot at the back. 6. Hands are to be kept outside the coverings. 7. Prescribed medicine should be taken regularly and exactly as directed. 8. Patient or parent must present a written chart of progress at each subsequent visit.

Cases with focal causes, such as oxyuris vermicularis, masturbation, cystitis, vulvovaginitis, anemia, malnutrition, neurasthenia and neuroses and neurogenic diseases require appropriate treatment. In cases of anemia and malnutrition, strychnine is a valuable adjuvant. Endocrine disturbances are given thyroid and posterior pituitary extract. Cases of highly acid urine, diabetes and nephritis are treated symptomatically. Idiopathic cases (undetermined origin) respond satisfactorily to atropine sulphate in large doses. The majority of cases of enuresis are amenable to treatment when diligence and perseverance are patiently observed by the physician.

Treatment of Summer Diarrhea in Infants and Children.—Donald Paterson (*Clinical Journal,* July 18, 1923) thinks that the loss of water by perspiration and otherwise during the summer months, and the failure of the attendants to furnish water for the baby to drink and so replace this loss, is a large factor in the mortality from summer diarrhea. He says: If this child were, say, two or three years of age there would be no difficulty in diagnosing the case earlier, as a bilious attack, and treating it accordingly. So should the infant be treated in the early stages. In the later stages, however, the problem of dehydration is to be dealt with, and this is the most important problem in summer diarrhea. The dehydration may be secured by the following methods:

1. *Intravenous injection of saline.*—This method is to be advocated only in very urgent cases. The saline is injected into the longitudinal sinus through the anterior fontanelle; this, however, requires great skill and asepsis and is accompanied by a certain amount of shock, and only a small amount of fluid may be injected at a time.

2. *Subcutaneous method.*—By this method a much larger quantity of fluid may be injected, the shock is less, there is less risk of sepsis, and the whole operation can be done by a person much less skilled. This is the method to be preferred if you cannot do the operation yourself and entrust it to a nurse.

3. *Intraperitoneal method.*—An extensive trial was given this method at Great Ormond Street in the summer of 1921, and on the whole the results were good in urgent cases. There is, however, a risk of infection, both by introducing organisms or from wounding the bowel itself, and it should be undertaken only when the subcutaneous method is not practicable. The advantages are that this method is quick, a large amount of saline being introduced at a known temperature. With the subcutaneous method, the introduction is slow and the saline has time to cool.

4. *Saline by the mouth.*—This is the method of choice for every child still able to swallow. The child is put to no inconvenience or risk. There is no pain involved. Very large quantities of fluid may be introduced this way. The saline is absorbed rapidly from a very large surface and the quantity absorbed automatically adjusts itself—no more being absorbed than the child requires. If the infant is offered sufficient quantities of saline by the mouth the dehydration is made good by this method much more rapidly than by any other method at present in use.

The saline should be half normal strength. It should be one half teaspoonful of salt to the pint. The bottle should be kept filled and beside the child, and he should be offered it as often as he is awake. At regular periods food should be offered the child also. The author states that he has known one infant of ten months to drink seventeen ounces of saline in two hours and gain one pound in the first day. As soon as the intestine has been washed and dehydration accomplished the child will fall asleep. Next he will commence refusing the saline and prefer his food. The number of stools will decrease.

The author believes that in most cases of summer diarrhea the children die, not of the upset or poisoning by infection, but by their mechanical result—dehydration.

Alkalescence of Cerebrospinal Fluid in Infancy.—A. Rálint (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) finds a constant carbonate content in the cerebrospinal fluid in infancy under normal conditions. In cerebral, especially inflammatory diseases the fluid shows a local acidosis, whereas other infectious processes do not show constant findings. Comparative investigations show that the acidosis of the cerebrospinal fluid does not run parallel with acidosis of the blood. In this respect, spasmophilia may be included among the cerebral processes. In other cases the presence of a generalized acidosis may be inferred from the presence of the acidosis of the cerebrospinal fluid. The method of investigation is so simple and the results are so accurate that it may be recommended for clinical purposes.

Intoxication Syndrome in Infectious Conditions in Infancy.—G. Bessau, S. Rosenbaum, and B. Leichtentritt (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) conclude that: 1. Infectious conditions which are associated with the intoxication syndrome (infectious intoxications) are not limited to any definite months of life nor to any definite time of the year. 2. The disturbances of temperature in the infectious intoxications are usually determined by the infectious noxa. 3. Exaggerated respiration is a symptom that, with few exceptions, is pathognomonic for the intoxication syndrome and at the most may be considered as being due to bacterial infection. 4. In infectious conditions the intoxication syndrome is just as little strictly associated with the administration of food as in the alimentary disturbances. 5. Their true cause is the same as in the cases due to alimentary causes: the exsiccation, the signs of which are never missing. 6. The causes of the exsiccation are the diarrheas and an increased excretion of water by the lung and from vomiting. 7. The elements of the intoxication syndrome in the picture of infectious intoxications should be combatted by correcting the loss of water. 8. Lactosuria occurs in both alimentary and infectious intoxication.

Nonspecific Serum Treatment in Infancy.—Berthold Epstein (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) states that proteotherapy in the form of nonspecific serotherapy also has a certain significance in infancy. In isolated forms of marasmus, which develop on the soil of a constitutional congenital inferiority, definite results were obtained in the primary atrophies and in the atrophies which appear in poorly flourishing premature children, in pseudopremature births, or in malformed children. But the conditions were different in the asthenic states, which are caused by exogenic, as for example infectious, injuries. In these cases an effect upon the body weight should be sought and this is often only transient. The cause of the disease itself, however, is not affected, the advance of the infection is not hindered, and the unfavorable outcome of the disease is occasionally delayed, but never prevented. This excludes the possibility that such an effect upon the body weight, which is not indifferent for the general condition, may be the decisive factor. More cannot be expected of proteotherapy in infancy. If these limitations are borne in mind this form of therapy is applicable in infancy.

Bacterial Asthma in Children. The Role of Infection and the Value of Vaccine Treatment.—Samuel Hurwitz (*Medical Clinics of North America,* September, 1922) finds: 1. That the attack of asthma usually begins after some respiratory tract infection; 2, that every subsequent attack is usually introduced by a new cold or bronchitis, generally at a season when nasobronchial infections are prevalent; 3, that many asthmatics are subject to more or less bronchitis during intervals between the attacks. The bronchitis should be considered as the inciting cause of the recurring attacks. Good results are often obtained, either with the eradication of a focus of infection surgically or with bacterial autogenous vaccines, or both in combination. In chronic bronchial infections, autogenous vaccines derived from the sputum are useful. Streptococci, both hemolytic and nonhemolytic, seem to predominate in the deep respiratory passages of these patients and pneumococci and the micrococcus catarrhalis are less common.

The treatment with autogenous vaccines is usually begun with small doses of pure vaccine at seven day intervals, each succeeding dose being regulated according to the reaction to the previous dose. The dosage ranged from fifty to one hundred million organisms to five hundred million to one billion bacteria. With this treatment, some patients were relieved for a little over a year and many had relapses. The cases that showed no improvement may be explained as follows: 1, Either the wrong bacteria were isolated; 2, or the bacteria isolated were only a part of the cause; 3, or the offending bacteria may not readily produce immune reactions; 4, or irreparable damage may have resulted in the bronchi and lungs from long continued bacterial invasion.

Tuberculosis in Childhood, Its Specific Diagnosis and Treatment.—Julius Grósz (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) arrives at the following conclusions regarding his experiences with the treatment with Koch's old tuberculin: 1. Koch's old tuberculin proved to be an excellent remedy in the treatment of tuberculosis in childhood, showing cures or, at least, considerable improvement. 2. The treatment is begun with very minute doses of old tuberculin (0.001 milligram and upward), which is slowly and carefully increased. The cases were treated for many months, sometimes for one to two years, up to the time of complete cure. 3. During the treatment only very slight rises of temperature of a few tenths up to half a degree centigrade are allowable; greater febrile reactions had best be avoided. 4. Only patients with a relatively good condition are suitable for tuberculin treatment, who are afebrile or subfebrile. Phthisical patients, in whom there is a marked destruction of tissue, are not suitable for this treatment. 5. Definite results were obtained in the occult cases, in whom the röntgenographic examination revealed only slight tuberculous changes. 6. Good results were obtained in the first and second stages of pulmonary tuberculosis, also in patients with so-called scrofulous changes in whom the Pirquet reaction was positive, then in the cases of tuberculous peritonitis and in the tuberculous skin affections. 7. The treatment with tuberculin aids the hygienic and dietetic measures.

Progressive and Malignant Endocarditis in Childhood.—F. John Poynton (*Lancet,* February 3, 1923) asserts that malignant endocarditis in childhood shows the same features as in the adult, though, as a rule, it is more rapid in its course. The symptoms are fever, sweating, anemia, purpura, Osler's spots, infarctions, optic neuritis and retinal hemorrhage, drowsiness, aneurysms, diarrhea, cerebral hemorrhage or embolism, hematuria, enlargement of the spleen, cardiac bruits and a continual excited action of the heart. This likeness to the adult cases is most significant when the close association with acute rheumatism is seen. The author holds that there is a rheumatic malignant endocarditis which may arise from the simple form or be primary in origin. He also believes that the mysterious cases of streptococcal origin in adults are either primary cardiac rheumatism of a malignant type, or, if not actually rheumatic, more closely allied to the rheumatic infection than any other. In other words, they are due to a strain of that group, just as there are different strains in other great infections.

Congenital Cyanosis and Congenital Heart Disease, Without Murmurs.—Mark S. Reuben and Walter C. A. Steffen (*Archives of Pediatrics,* December, 1922) find that in any case of congenital cyanosis presenting other symptoms which suggest the presence of congenital heart lesions (enlargement of heart as shown by x rays, dilatation of the capillaries of the eye, clubbing of fingers, erythrocytosis, high hemoglobin content, osteoarthropathies, increased alveolar carbon dioxid tension, accentuation of the second pulmonic sound, etc.) without any murmurs, in most cases, is associated with pulmonary stenosis or atresia and a defect in the interventricular septum and patent foramen ovale; very often these lesions are associated with saddle aorta and persistent ductus arteriosus. In the great majority of cases the lesions are multiple. Sixty to seventy per cent. of these cases do not complete the first year. Congenital heart murmurs not infrequently disappear; they may leave no semblance of previous cardiac deformity or they may leave behind all the symptoms. It is a striking fact that the signs and symptoms very often do not correspond.

Regulation of the Respiration Frequency in the Newborn and During the Early Years of Life.—T. Hishikawa (*Schweizerische medizinische Wochenschrift,* March 29, 1923) shows that in the newborn the respiratory frequency is arranged to a limited zone of frequency, which frequency varies in different individuals. During the course of the first few days this range of variation is diminished by those with a greater frequency approaching the others. The average rate of respiration sinks from the day of birth to the third day of life from 78 to 61 and the variation lies between 106 and 70 on the seventh day, to remain at about this level during the first year of life. During the course of the second and third years the average and the variable values sink to about half the values of the first year of life. The duration of the respirations which follow one another shows sudden changes during the entire first year of life, which diminishes rapidly in the succeeding years. These phenomena should be considered as a gradual adaptation and adjustment of the regulatory mechanism of the frequency of breathing.

RESPIRATORY DISORDERS.

Arena's Method of Homogenization of Sputum for the Purpose of Demonstrating Tubercle Bacilli.—Alexander Roseblüth (*Wiener klinische Wochenschrift,* February 8, 1923) recommends Arena's method, which is carried out as follows: five or ten c.c. of sputum, respectively, are mixed with forty-five and ninety c.c., respectively, of a ten per cent. ammonium chloride solution for five to ten minutes until homogenization results; if this is not sufficient, ten to twenty c.c. of glycerin are added. This mixture is put into an incubator for thirty or sixty minutes, respectively, at 37° C. and then centrifugalized at a speed of 2000 to 2500 revolutions. The fluid is then carefully poured off and the sediment is smeared on a glass slide, where it is fixed by heat. The smear is then stained by the Ziehl-Neelsen method and it is then decolorized by at least 2.5 per cent. nitric acid.

Influence of Glands With Internal Secretions on the Respiratory Exchange.—David Marine and Emil J. Baumann (*Journal of Metabolic Research,* July, 1922) produced a prolonged absolute rise in heat production in eighty-two per cent. of thirty-three rabbits in which both suprarenal glands were completely removed, and in forty per cent. of rabbits where the suprarenal function was crippled by freezing. The rise in heat production may last from a few days to several months, the longest period studied being twenty-three weeks. This increase in heat production appears to depend partly upon the increased rate of discharge of the iodine containing hormone from the thyroid. Suprarenal injury does not impair the ability of the thyroid to store iodine or to produce this hormone. Infection, trauma, nerve injury, muscular movement and diet are not essential factors in the increased thermogenesis following suprarenal injury.

What Should Be Done With the Healthy Epiglottis After Total Extirpation of the Larynx?—Karl Kofler (*Wiener klinische Wochenschrift,* January 4, 1923) describes a case in which the epiglottis that was left behind after a total extirpation of the larynx made swallowing very difficult and had to be removed subsequently. Therefore, inasmuch as the epiglottis is a superfluous organ after this operation, the author advises its extirpation, except in those special cases, where it is advantageous to retain it.

Fatal Congestive Hemorrhages Into the Lungs and Central Nervous System From a Momentary Excessive Bodily Exertion and Its Relationship to Perthes's Pressure Congestion.—E. Hedinger (*Schweizerische medizinische Wochenschrift,* August 24, 1922) describes a case, in which extensive pulmonary hemorrhages and less extensive hemorrhages into the temporal gyrus and into the cervical portion of the spinal cord occurred as a result of an enormous exertion, associated with a marked venous hyperemia of the lungs and of the veins of the skull and the vascular apparatus through rhexis and diapedesis. On the other hand, in compression of the trunk there is no marked cyanosis of the face and no multiple hemorrhages into the skin and the mucous membranes of the head and neck in Perthes's pressure congestion; in the latter, there are also no hemorrhages into the brain and the spinal cord.

Problem of the Tonsil.—Fritz Schlemmer (*Wiener klinische Wochenschrift,* September 21, 1922) shows that the palatine tonsil, just like the rest of the lymphatic substance of the oropharyngeal cavity, does not possess sufficient afferent lymph vessels: the efferent flow from the tonsils proceeds exclusively centripetally to the anterior superior jugular glands and there is no centrifugal current to the pharynx. The lymphatic tracts of the tonsils, just like all such tracts of the skin or mucous membranes, begin blindly and an open communication toward the pharynx does not exist. The author, therefore, rejects the generally accepted conception of the tonsillar apparatus as a lymph gland tissue, but considers it as a part of the total mucosa. He therefore considers himself justified in his position against the theory of anginosis.

Diagnosis of Septic Sinus Thrombosis.—William Milligan (*British Medical Journal,* September 9, 1922) asserts that typhoid fever is the disease with which septic sinus thrombosis is most likely to be confused, especially during the first week of typhoid fever and if the ear happens to be suppurating; the presence of a positive Widal reaction, petechiæ and the absence of very marked fluctuations in the temperature, with rigors or chills, aid in the making of the diagnosis. The septic sinus thrombosis is differentiated from a central bronchopneumonia by the persistent cough, the rusty sputum and the more even temperature. The examination of the blood and the presence of the Plasmodium malariæ serve to differentiate the septic sinus thrombosis from malaria. In rare cases of severe gastric attacks in infants and young children, especially in the presence of running ears, the septic sinus thrombosis is likely to be overlooked. Typical cases are usually recognized without difficulty, but atypical and latent cases may present extremely complex problems. The author does not hesitate to perform an exploratory operation to expose or actually slit up the sinus merely for the purpose of making the diagnosis.

Prophylaxis of Diphtheria.—F. v. Werdt (*Schweizerische medizinische Wochenschrift,* November 2, 1922) discusses the contagiousness of diphtheria, particularly the part played by the carriers of the bacilli, based partly on his own observations in schools, whereby he found 12.5 to 31 per cent. of carriers, according to the stage of the epidemic. Inasmuch as the determinations of virulence in regard to the decision of the question as to which of the carriers are capable of transmitting the infection, are too expensive and time consuming, all of the carriers must be treated just as if they carried virulent strains of bacilli. The author then discusses the difficulty of distinguishing between the true diphtheria bacilli and the diphtherialike bacilli. In the examination of a great number of specimens the morphological characteristics must be the decisive factor. None of the remedies proposed act as sure disinfectants in every case, but many are effective in some cases. Sprays and instillations into the nose seem to act more effectively than touching or painting of the tonsils. The other important factor in epidemics is the cutaneous inoculation according to the method of Schick in order to show all those that are susceptible to diphtheria and their immunization according to the method of V. Behring.

Studies on Bacterial Nutrition.—Theodor Thjotta and O. T. Avery (*Journal of Experimental Medicine,* November, 1921) report that the growth accessory substances which occur in blood have been found to exist also in plant tissue. Raw potato can replace blood in the cultivation of Bacillus influenzæ.

Pfeiffer's Bacillus and Influenza.—Bacteriological examinations of lungs at necropsy by S. W. Patterson and F. E. Williams (*Lancet,* October 14, 1922) over a period of twelve months, during which time three distinct prevalences of influenzal attack were noted, yielded information which supports the view that the incidence fluctuations of the Bacillus influenzæ as a lung parasite are independent of the particular pulmonary condition associated with it.

Bronchial Asthma and Fever.—P. F. Holst (*Norsk Magazin for Laegevidenskaben,* August, 1922) in his study of the relation of rise in temperature to be the periodical disappearance of asthmatic attacks offers the following explanation: In the same way that anaphylactic shock may produce a state of antianaphylaxis in guineapigs, so that injections with the same albumen that in the first instance produced the shock may be made later without any recurrence of the shock, fever may produce antianaphylaxis in asthmatic patients, that will last for some time. The fever may have formed active antibodies. If the question is considered from another angle, i. e., the increased vague innervation present in most asthmatic attacks, then not only adrenalin, but any agent that stimulates the sympathicotonia will have antiasthmatic action. It is possible that fever might produce such a sympathicotonia—or the fever producing agent. The symptom complex of fever has also been interpreted as a result of sympathicotonia. The favorable effect of iodine in these cases which has always been considered due to the effect on the bronchitis, may also be due to its stimulating effect on the adrenals. Also the favorable effect of iodine on asthmatic patients might be traced to increased thy- excluded.

Changes in Mothers' Milk During Lactation.—W. Birk (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) shows that human milk and cow's milk behave alike in regard to their content of nutritive substances and salts during the course of lactation. Heretofore this has been a moot question. He also shows that human milk does not lose any of its richness in salts and albumen even after a lactation lasting three years.

Secondary Infections Complicating Pulmonary Tuberculosis.—R. C. Wingfield (*Lancet,* January 13, 1923) does not advocate the administration of autogenous vaccines in every case of pulmonary tuberculosis where the character and bacteriology of the sputum lead one to suspect a secondary infection, but rather tries to show that there are certain types of cases in which, even under sanatorium treatment, secondary infection of clinical importance can be recognized and will respond to vaccine treatment.

Changes in the Leucocyte Picture Following Injections of Gelatin in Tuberculous Children.—Paul Heim (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) shows that there is, as a rule, an increase in the number of lymphocytes following the injection of gelatin in the benign cases, whereas the cases showing a bad prognosis are characterized by the fact that there is absolutely no effect upon the lymphocytes and they may even be diminished in number. With a reasonable amount of care this reaction may be of prognostic value and it may also be used as a therapeutic aid in miliary tuberculosis.

Rapidity of Sedimentation of the Erythrocytes in Pulmonary Tuberculosis.—Hans Poindecker and Karl Siess (*Wiener klinische Wochenschrift,* December 14 and 21, 1922) come to the following conclusions in regard to the practical value of this test and in regard to in what condition it is applicable: 1. The rapidity of the sedimentation of erythrocytes in citrated blood varies within certain limits even in healthy individuals. 2. On the exclusion of other causes favoring the sedimentation, an increase in the rapidity of the sedimentation favors the assumption of a disease process in the lung associated with a tissue necrosis of exudation; this test gives no information regarding the specificity of the pulmonary disease and not always sufficient information regarding the nature of the pulmonary involvement. 3. It should be used only with great care in the diagnosis of preeminently fibrous forms of tuberculosis; higher sedimentation values allow the drawing of conclusions regarding its activity. 4. The beginning phthisis can be differentiated from the benign apical tuberculosis by the sedimentation test. 5. It is a delicate indicator of the activity and regarding the progression of a phthisical pulmonary involvement and has a definite value in the prognosis of these conditions. 6. The determination of the sedimentation rapidity affords important information in the recognition of occult focal reactions and in the guiding principles for the carrying out of a specific treatment. 7. This test is easily carried out in practice and should not be omitted in any examination of the lungs; but it is valuable only when carried out with the most painstaking care and when all other factors favoring the sedimentation of the erythrocytes are roid activity leading to sympathicotonia.

Summary of Symptoms of Encephalitis Lethargica*

By FRANCIS X. DERCUM, M. D.,
Philadelphia.

The initial symptoms of encephalitis lethargica are generally vague and not characteristic. They may, however, be featured by a sense of illness, weakness, headache, general pains, chills, loss of appetite, nausea, symptoms of invasion of the respiratory passages (i. e., increased discharge from or catarrhal inflammation of the nasopharynx, nasal and accessory sinuses, of the auditory passages, of the bronchial tubes and even of the pulmonary tissue); at other times of irritation or invasion of the gastrointestinal tract. In many cases the onset is not featured by any of these symptoms; all socalled prodromata may be absent.

With or without them, we note among the earliest symptoms dimness of vision, diplopia, partial ptosis, faint cranial nerve palsies; perhaps a little apathy, a little confusion, perhaps insomnia; then headache, somnolence and, rarely, convulsions.

Fever also is present though this fever is rarely high and is quite irregular in its course. Quite commonly it ranges from 99° to 101° or 102°. Very rarely is it high; in only one of my cases did it reach 104°. Not only is its course quite irregular, but its duration, too, is uncertain; frequently only a few days, sometimes a week or two and rarely longer. Respiration and pulse show but little change, though sometimes a slight rise in frequency of both are noted.

Among the most striking symptoms in the average case is the somnolence, but of equal prominence and indeed at times so early as to precede the somnolence are the eye symptoms. These consist more especially, as already indicated, of diplopia, ptosis, dimness of vision. The diplopia is frequently so pronounced that the patient may of his own accord complain of it or the divergence of the globes is so marked that the persons about the patient may call attention to it. Quite commonly the symptom is transitory, i. e., lasts but a few hours or a few days and then disappears, but very frequently the patient retains a very clear memory of its occurrence. The strabismus may be convergent or divergent; the diplopia homonymous or crossed. It is usually the most striking and the most constant of the ocular symptoms; also the very first to attract attention. It should be added that instead of being transitory and fugacious, it may be persistent, though this is relatively infrequent.

The ptosis is also an early symptom. It may precede, follow, but more frequently accompanies the diplopia. It is not a frank palsy but merely a paresis. The eyelid falls, but as a rule the eye is but half closed, the cornea but half covered. It may affect one eye, though more frequently both. It may vary—sometimes markedly—in degree on succeeding days or even during the same day. Finally, it is a symptom which on the whole is much more persistent than the diplopia. In cases in which diplopia is absent or, having been present has disappeared, marked asthenia of the extrinsic muscles of the eye can, as a rule, be readily demonstrated. If the patient be directed to look upon an object to one side so that an effort at decided lateral rotation of the eyeballs is necessary, it will be noted that the muscles become fatigued very quickly; sooner or later the globes return to the median position.

The dimness of vision I regard as a symptom of great importance, as it is not only an early and striking symptom but one which may be present when both the diplopia and the ptosis may be absent or but slightly evident. The dimness of vision, too, is likely to be misinterpreted and may be referred to possible changes in the optic nerve or retina and yet an ophthalmoscopic examination of these structures may reveal them to be normal. A brief examination, however, shows that the dimness of vision is due to a paresis of accommodation and frequently also of convergence. There is an undoubted paresis of the ciliary muscle, hence the feebleness of accommodation and the resulting lack of clearness in vision. The iris seems also in many cases to share in this paresis.

In striking contrast with the paresis to accommodation is the preservation of the light reflex. In by far the larger number of cases the light reflex is clearly and definitely intact, and this gives rise to a

---

reversed Argyll-Robertson pupil. On the other hand, to show the vagaries in the ocular symptomatology of encephalitis, I should state that the opposite dissociated palsy, namely loss of the light reflex and preservation of accommodation—a true Argyll-Robertson pupil—has been recorded by both German and Italian observers though it must be conceded that such an occurrence is excessively rare. Finally like all the other eye palsies it may prove to be temporary.

As regards the impairment of vision one important caution must be added. In a limited number of cases, a true amblyopia and even a true amaurosis may be noted. This, however, like the other symptoms, is transitory and is unaccompanied by any changes in the fundus. Very rarely, however, a true swelling of the disc has been noted, or there has been a blurring of the edges of the disc with tortuosity of the retinal veins and pallor of the temporal half of the disc, perhaps a slight hyperemia or a slight neuritis. On the other hand, a retrobulbar neuritis has been noted or even a frank double optic neuritis with small hemorrhages. Such findings, however, appear to be secondary to gross changes within the cranium, such as meningitis, marked involvement of the ears and consequent involvement of the great venous sinuses and are not directly attributable to the encephalitis but to its complications.

In addition to the involvement of the intrinsic and extrinsic muscles of the eye there may be involvements variously of the seventh, eighth, ninth, tenth, eleventh and twelfth cranial nerves. These are indicated by facial palsy or rather by facial paresis often faint in character, by dulness or impairment of hearing, by loss or impairment of the sense of taste, by difficulty of swallowing, by paresis of the soft palate, of the larynx, or of the tongue. Extensive involvement of these structures is infrequent though it now and then occurs.

In regard to the other and later oncoming motor phenomena, the motor sequelæ, such as the Parkinsonian rigidity, catatonic fixations, choreiform, clonic and athetoid movements, tremor and irregular voluntary movements, and the rarer hemiplegias, monoplegias and contractures, and the epileptiform convulsions, time will not permit of an extended consideration.

The motor disturbances are in the main referable to lesions of the striatum. The Parkinsonian and allied symptom groups point directly to lesions of the lenticular nucleus, more particularly to the pallidum and the pallidal tracts. It would appear that the innervation of the muscles of the head, trunk and extremities depends both upon the impulses derived from the motor area of the cerebral cortex and upon those derived from the pallidum, and that the normal muscle tonus is the resultant of the interaction of these two series of impulses, and which appear to exercise a mutual inhibitory action upon each other. In destructive lesions of the pallidum, therefore, the muscles are given over to the impulses derived from the cerebral cortex and the rigidity of the Parkinsonian symptom complex so often observed after encephalitis lethargica is due to the excessive preponderance of the cortical motor innervation; it is a true motor cortex or pyramidal hypertonia. Very significant is it also that in this condition the tendon reflexes are but little modified, possibly moderately increased, while the Babinski sign is invariably absent. The presence of the Babinski sign points to pyramidal involvement but such involvement it would appear is rare. The same explanation applies of course to such symptoms as catatonic fixations and cataleptoid phenomena. The choreiform, clonic, athetoid and allied disturbances of motion are, I believe, to be referred to lesions of the putamen and caudatum, that is, to those portions of the striated body that lie external to the pallidum.

The rare hemiplegic, monoplegic and allied symptom groups like the epileptiform attacks are of course to be referred to pyramidal and cortical involvement. The motor disturbances referable to lesions of the striatum it should be emphasized greatly preponderate in this disease.

Sometimes symptoms are also present clearly pointing to involvement of the membranes, i. e., to the presence of a meningitis. Suffice it to say that the symptoms present in a given case may point to a diffuse involvement of many structures and that special symptoms merely indicate the accentuation of the damage done by the infection to certain portions of the nervous system; it may be to the pallidal system or to the pyramidal system, or it may be to the caudate nucleus or perhaps to the cerebral cortex, or to all of these structures variously combined. It may be added that cerebellar symptoms also may occur though they are admittedly unusual.

Turning our attention now to the somnolence we find that it at times precedes, at times follows, but most frequently accompanies the ophthalmoplegia. This somnolence consists in the majority of cases merely of sleep; sometimes this sleep is very profound but it is not coma nor even stupor nor torpor. The patient is aroused by stimuli of various kinds; e. g., by speaking to him loudly, by shaking him, by pinching or by pricking. Usually he can be made to answer questions. He chews food that is placed in his mouth, swallows, is continent, does not soil his bed or his clothing. At times he can even be made to sit up in bed and it may be to walk.

Instead of somnolence, the patient may suffer from insomnia. If insomnia be present, it is usually associated with excitement and at times with confusion or delirium.

The question now arises are there any sensory phenomena present in encephalitis lethargica. It may be definitely stated that marked sensory losses are not a feature of encephalitis. The patient's somnolence, however, is such that sensory phenomena unless painful are usually not noted. Upon a few occasions various paresthesias have been observed such as formication, sandy feeling, and at others a sense of tightness or tension; rarely has hyperesthesia been noted and then is painful in character. Equally rare have been pains suggesting a central origin; namely due to lesions of the thalamus. Sometimes a pain suggesting a root pain and somewhat more frequently pain suggesting a neuritis is observed. On the whole, however, painful manifestations are found to be the exception.

Every now and then spinal symptoms are especially prominent. The symptoms depend of course upon the special structures of the cord involved and upon the degree of this involvement. Palsies suggesting diffuse or transverse lesions of the cord may, though rarely, be observed. Sometimes the symptoms point to the involvement of special columns as in a case of my own in which the symptoms suggested an ataxic paraplegia and in which the sphincters also were affected.

The peripheral nerves likewise may present symptoms in encephalitis though this complication is quite infrequent. However, a frank neuritis with its attendant pain and other symptoms may occur. Always the other symptoms showing unmistakably the existence of encephalitis lethargica are present; the neuritis merely gives a special picture to the case.

The examination of the spinal fluid deserves a brief mention. First, it is not characteristically changed. It is usually clear. Its pressure is normal, sometimes slightly increased, sometimes decidedly increased, though this is the exception. No increase or a moderate increase of globulin or lymphocytes may be noted. If these elements are decidedly increased, it probably indicates a more marked involvement of the membranes. I have in almost every one of my cases been able to secure an examination of the spinal fluid. This examination has commonly not yielded significant results. Studies of the blood in my cases have also failed of definite information; commonly merely a variable degree of leucocytosis, at times a reduction in the red cells and hemoglobin, but there were no characteristic changes.

Regarding spinal fluid examinations in encephalitis lethargica they should, I am convinced, be made with caution. In my judgment only enough fluid, at most four c. c., should be removed. I think it very probable that if the intradural pressure be suddenly and greatly reduced, the diffusion of the germs of the infection will be greatly favored. Further, I am quite convinced that spinal drainage in encephalitis not only does no good but may be productive of harm.

Unfortunately time will not permit of an adequate consideration of the course of the disease, of its spontaneous recoveries or fatal endings, of its sequal so often persistent and chronic, nor of the distressing recurrences of symptoms, often late, in patients who had previously made an apparent recovery. First, the course of the disease is admittedly irregular. Time and again cessation of progress or apparent recovery are observed only to be followed, often many months later, by a distressing recurrence of symptoms. In my experience complete recovery is rare, and it cannot be said in any given case that the danger of recurrence has passed away until a long time has elapsed. Very few cases are left without some traces of the affection. Not infrequently I have noted in cases with recovery slight but persistent pupillary phenomena, or slight flattening of the features as though the facial muscles had never fully recovered their normal tone; or it may be that the attitude of the patient is faintly suggestive of the Parkinsonian symptom group. So slight a symptom, for instance, as the failure of the arms to swing, while walking, in unison with the contralateral leg may be a sufficient hint of slight, though permanent, damage.

I need hardly state in conclusion that quite a large number of patients die in the early period of the disease. My impression is that in the year 1919, when the present epidemic first made its appearance in this country, that a larger proportion of patients died than in the years following. The cause of death is to be ascribed at times to exhaustion and intoxication; at others directly to the damage done to the nerve centres. Sometimes visceral lesions feature in the death though this is unusual. The cases which survive and which persist with slight or pronounced sequelæ appear to live with varying periods of improvements and accentuation of symptoms for a number of years. It is too early as yet to say much definitely as to the eventual outcomes.

Catalepsy in Epidemic Encephalitis*

A Clinical and Pathological Report of a Case of the Cataleptic Type with an Explanation of This Phenomenon

By JOHN H. MUSSER, JR., M.D.,
and A. E. BENNETT, M.D.,
Philadelphia.

In the multiplicity of writings on the symptoms of epidemic encephalitis the term catatonia has been used rather loosely to describe a certain type of disease. One hesitates before adding more to the already voluminous literature of acute epidemic encephalitis, but with the feeling that any report which tends to clarify the existing literature or add new knowledge to this remarkable disease is justifiable, we offer the following report:

Catatonia as a symptom has been reported in many organic cerebral affections viz., general paresis (1), uremia (2) and a tendency to maintain given positions (catalepsy) has been observed in this hospital in senile deterioration and cerebral thrombosis. Hoch (3), Kirby (4) and others have shown that negativistic phenomena and catatonic reactions occur in organic deliria and toxic infectious psychoses as well as in benign emotional stupors. It is not surprising then that among the protean manifestations of encephalitis cataleptoid symptoms are seen.

Early in the English epidemics several writers described interesting cateleptic types: Balton and Still (5), Hall (6), and Wilson (7). Wilson concluded that reduction of mental activity to the level of automatism was common and catatonia was a frequent symptom of the disease. Many authorities in this country have observed cataleptic states and reported

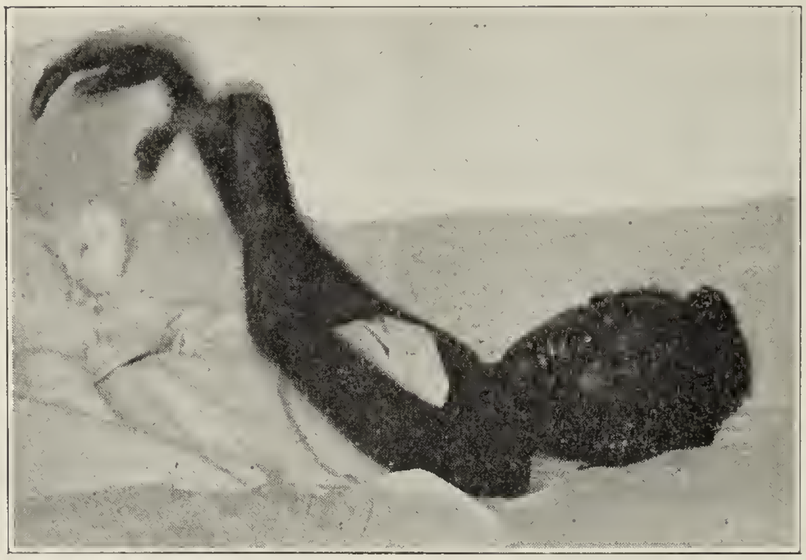

Fig. 1.—Shows the patient in stupor late in the disease with fine tremors of the hands but still maintaining given positions.

cases of this type: Barker (8), Kennedy (9), Hohmann (10), and bond (11). Hohmann states these have been mistaken for schizophrenic reactions. Tilney and Riley (12) report an instructive case with choreic movements at the outset, shortly followed by stupor with hypertonic rigidity and later showing catalepsy. This sequence of symptoms seems usual in this type and was the order observed in our case. They suggest a clinical cataleptic type in their classification and believe the prognosis is less severe in this form than is usually supposed. On the other hand Bassoe (13) says: "In severe cases the whole body becomes rigid and all movements slowed, a condition resembling catatonia and advanced paralysis agitans rigidity occurs. A good imitation of flexibilitas cerea." Jones and Raphael (14) in writing on muscular hypertonicity and stupor in encephalitis associate catalepsy with substupor types. Sicard and Bollack (15) report a case that presented fixed attitudes and recovered but with a paralysis agitans syndrome. Petren and Brahme (16) in a recent article report a case in which there was almost complete immobilization of the body (only ocular, respiratory and swallowing movements being conserved) which persisted for months with no true paralysis. Improvement resulted but Parkinsonian-like rigidity remained as a sequel. They assumed from clinical observation that the symptoms are due to extrapyramidal lesions and that lesions of this system must be capable of causing such an enormous hypertonia that not even passive movements are possible.

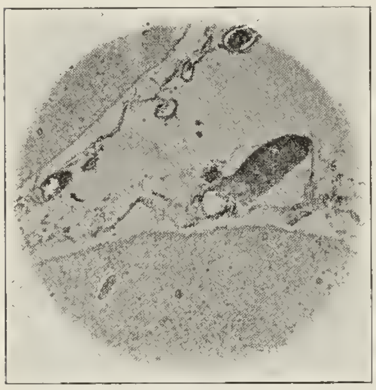

Fig. 2.—Meninges over cortex. Shows slight infiltration with round cell elements.

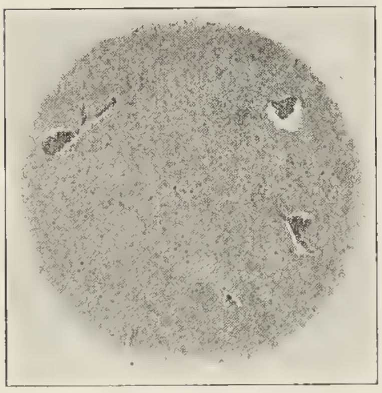

Fig. 3.—Pons. Shows typical findings in epidemic encephalitis.

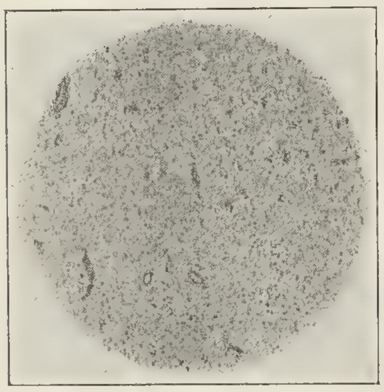

Fig. 4.—Thalamus. Note intense dotting with round cell elements and lessened number of ganglion cells, and vessels with collars of cells.

Kirby and Davis (17) have written very clearly upon the subject. They object to the clinical grouping "lucid catatonic form," reasoning that this is not a distinct type but only different in a superficial way from other forms. They also with justification object to the misleading term catatonia in describing patients of an organic psychotic type who tend to maintain a certain fixity of position. They, as well as Tilney and Riley (12), associate this flexible hypertonus with paralysis agitans symptoms, especially the rigidity. Furthermore, they have observed no symptoms of negativism in their patients nor any of the characteristics of catatonic stupor as seen in dementia precox.

Various interpretations of the mechanism concerned in the production of this amyostatic syndrome — hypermyotonia with rigidity and catalepsy, have been offered. Tilney, Riley, Howe, Kirby and Petren are of the opinion that disease of the extra palliospinal system is entirely responsible for these phenomena. Wechsler (18) is doubtful whether involvement of the extrapyramidal system alone explains it. He states it is more likely a true cerebral condition or interference of cerebral function and consequent liberation of uncontrolled unconscious activity as illustrated in hypnotic catalepsy. He quotes Southard's and Alzheimer's pathological studies in catatonic dementia precox as a basis for this conclusion. The close similarity of our case to other cases in which in all there was marked evidence clinically of striated system inflammation and the pathological findings in our case—extensive degeneration in the basal ganglia especially the thalamus and substantia nigra (19)—leads us to agree with Kirby, Tilney, Petren and others that cataleptic symptoms in the encephalitis are part of the picture of a severe Parkinsonlike syndrome or a mixed striatal type of the

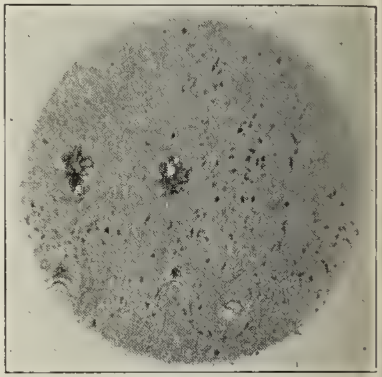

Fig. 5.—Normal substantia nigra.

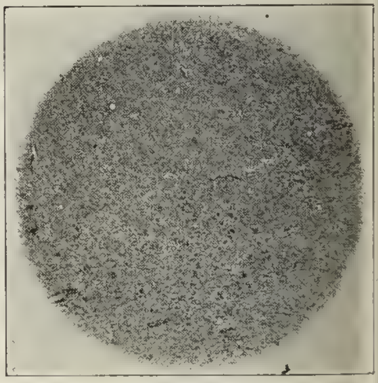

Fig. 6.—Substantia nigra showing almost complete absence of normal cells and intense dotting with round cell elements.

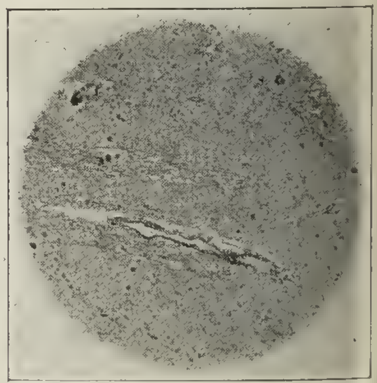

Fig. 7.—Substantia nigra, showing lessened number of normal cells, increase in round cells, and vessels with perivascular infiltration beside a strand of fibres of the third cranial nerve.

disease. Furthermore, there may be varying degrees of this hypermyotonia in the disease dependent upon the location and extent of inflammation present in the striatal system.

CASE.—A. B., colored female, sixteen years of age, was admitted to the Philadelphia General Hospital, March 9, 1923. The following history was obtained from the mother: The patient was a normal, healthy girl prior to her present illness which began in the latter part of February, 1923, with a slight cold. On February 27th, the mother noticed the patient persisted in smacking her lips, this continued for a day, then it was noticed she acted queerly; leaving the house to go outside and back again, next she became dizzy, nauseated and vomited. On the evening of March 1st, on returning from school, she expectorated constantly; the mother also noticed excessive salivation. On March 2nd, peculiar body movements were observed, irregular movements of head, eyes and protrusion of the tongue. At this time the patient appeared overactive and excited (played the victrola constantly, running about the house, and other activities). She was then taken to a physician who told the mother he thought the child had St. Vitus dance. The body movements became more pronounced and the arms and legs became involved. On the morning of March 3rd, on arising she fell asleep while dressing and complained of pain between her shoulders. She gradually became more drowsy and the body twitchings more pronounced, (mother feared she would have convulsions). The salivation persisted and the lethargy became more profound so that she refused food; body movements ceased and she remained mute, in which condition she was admitted to the hospital. The patient never complained of headache nor any oculomotor symptoms.

Examination on admission.—A young normally developed negro girl, lying immobile in bed like an image. She could be aroused to obey simple commands such as showing her tongue or opening her eyes, but executed these with greatly delayed reaction time; she would not answer questions, but nodded her head in answer; there seemed to be some active negativism in attempting to examine the patient. There was general body rigidity, her arms at first resisted passive motion and were held in catalepsy for indefinite periods (this picture was so striking that the receiving ward physician hesitated in assigning the patient to the medical wards until he obtained the above history). Later cogwheel resistance was pronounced in the arms. No myoclonic twitchings or tremors could be seen. Her general physical examination was essentially normal.

Her neurological examination disclosed the following: Eyes; pupils irregular in contour, reacted sluggishly to light, accommodation not tested; a persistent lateral nystagmoid oscillation was present during the entire illness, excessive lachrymation and salivation were noted, all other cranial nerves were negative. Reflexes: The biceps and triceps on both sides were active; abdominals: uppers were present and the lowers absent; the patellars were overactive on both sides, the plantar reflexes were flexion; an abortive ankle clonus was present on the right side and absent on the left; bilateral Kernig's sign was present.

Progress of the case.—On the 10th her lethargy had increased to stupor; she could only be roused by strong stimuli; she continued to show the general body rigidity resembling the waxy flexibility of catatonia. On the 12th she was in coma, her deep reflexes continued overactive, the Kernig was increased, the cogwheel phenomenon and cataleptoid symptoms persisted; at this time fine rhythmic tremors of the outstretched fingers were noted. The plantar reflex had disappeared on the right but irritation on the right brought out a crossed reflex of the left side in the form of a fine rhythmical tremor of the toes. On the 14th (Fig. 1) her tremors were more marked, the catatoniclike symptoms persisted, but her outstretched arms slowly descended to the bed as though from weakness, the pupils failed to react to light and abdominal reflexes were abolished. On the 16th following spinal drainage she came out of her stupor, answered questions and obeyed commands; this lasted only a few hours; she then relapsed into increasing coma and on the 18th there developed signs of a bronchopneumonia, the patient becoming gradually weaker and died on the 21st.

Her temperature on admission was 98° F, but soon rose to 103° (by axilla) and continued between 102° and 107° most of the time; for several days ranged from 105° to 107°. The pulse rate was between 130 and 150, with respirations 20 to 25, going up higher with her penumonia. At first she had urinary retention and later incontinence. Nasal tube feedings were required during the entire time.

Laboratory findings.—Several spinal punctures with drainage were done. The fluid was always clear and never under increased pressure, in fact at times there was difficulty in obtaining enough for the examinations. The first examination showed 9 cells per cm. with no globulin; two other counts showed eleven and 36 cells respectively with increased globulin. Wassermann in blood and spinal fluid was negative, colloidal gold showed a mildly luetic type of curve, smears for tubercle bacilli and other organisms were negative. The pH value of spinal fluid was reported in one at 7.4 and in another specimen (collected under oil) at 21° C. 7.75 and at 38° C. 7.5. Urinary examinations except for a trace of albumin were negative. Spinal fluid chemistry showed a urea of 18 mgm. and sugar of 85 mgm. per 100 c. c. The blood picture showed, hemoglobin 86, leucocytes 6,950, polymorphonuclears 65 per cent., lymphocytes 35 per cent. The carbon dioxide tension of the blood plasma was 49 per 100 c. c. A throat culture showed almost a pure strain of hemolytic streptococcus with a few colonies of Freidlander's bacilli. The blood pressure varied from 110/80 to 90/70. Examination of the eye grounds revealed normal fundi.

A clinical diagnosis of acute epidemic encephalitis and terminal bronchopneumonia was made. A necropsy four hours after death revealed the following gross and microscopical findings of the viscera: Aorta—atheroma; heart—hypertrophy; chronic interstitial myocarditis; lungs—bilateral bronchopneumonia; spleen—acute diffuse and chronic interstitial splenitis and congestion; kidneys—acute parenchymatous degeneration; liver—cloudy swelling and congestion.

The following brain and spinal cord studies were done by Dr. N. W. Winkleman, neuropathologist of the Philadelphia Hospital.

Grossly the brain and cord appeared normal. Routine sections were taken from all parts of the cortex, the basal ganglia, midbrain, pons, medulla and spinal cord and stained with toluidin blue, cresyl-violet, hematoxylin and eosin, Weigert and Sharlach R.

The meninges showed in places a slight infiltration with round cell elements consisting of lymphocytes and a few plasma cells, but nowhere was this very intense (Fig. 2). The cortex itself was devoid of pathology except a few petechial hemorrhages which were fresh and were probably agonal. The medulla oblongata showed but a few vessels whose adventitial lymph spaces contained round cell elements, while the spinal cord was entirely normal. In the pons the evidences of encephalitis of the epidemic type were present as shown in Fig. 3. It was in the midbrain and in the basal ganglia that the pathology was most marked. In the latter the thalamus was most intensely involved and in places the thalamic structure was almost unrecognizable as shown in Fig. 4, where the infiltrating cells are seen not only around the vessels but in the tissue substance itself with a disappearance of many of the thalamic ganglion cells. In the striate body the evidences of encephalitis were present but to a much less degree. In the mesencephal the substantia nigra was particularly involved resulting in an almost complete disappearance of the normal pigmented cells with replacement with lymphocytes and glial nuclei as shown in Fig. 6 (compare with Fig. 5, which is the normal substantia nigra at about the same level). Perivascular infiltration was present here also and Fig. 7 illustrates the proximity of such a vessel to the emerging fibres of the third nerve and gives the probable explanation for the frequency of partial third nerve symptoms in epidemic encephalitis where a localized meningitis in the interpeduncular space is not present.

CONCLUSIONS

1. We have observed a case of epidemic encephalitis showing extreme muscular hypertonia, rigidity and catalepsy. We were able to demonstrate that severe localized lesions of the striate system are capable of causing this amyostatic syndrome. We believe that patients of this type that recover will show paralysis of automatic association movements, rigidity, tremors or other residual Parkinsonianlike forms. We are of the opinion that the immediate prognosis in this type should be guarded and that this represents a severe type of disease, but recoveries have been reported.

2. Generalized hypertonus of the muscular system is a frequent symptom of encephalitis. It may reach a degree sufficient to cause the patient to maintain given positions or catalepsy. It seems usual for this type to have choreiform movements early in the disease followed by stupor, muscular rigidity, hypermyotonia and cataleptoid phenomena.

3. This hypermyotonia with rigidity should not be mistaken for a schizophrenic reaction. The history with evidence of a febrile infectious process, the association of cogwheel resistance, rigidity, tremors of a paralysis agitans type, myoclonic twitchings or other neurological signs with the spinal fluid examinations should differentiate the case from catatonic dementia precox while the absence of other schizophrenic phenomena should make the diagnosis certain.

The Incidence of Acute Epidemic Encephalitis in Bellevue Hospital in the Months of January, February, March, 1923

By RAYMOND S. CRISPELL,

New York.

In the first quarter of 1923 there was discharged from Bellevue Hospital a total of fifty-five patients on whom the diagnosis of epidemic encephalitis was made. This does not include the admissions of encephalitis during this period, which would probably bring the total above that given. Neither does it include the discharges from the psychopathic division of the hospital, which keeps its records separately, but which also had its share of admissions of encephalitis. When one compares the total admissions in 1921 and 1922 of encephalitis with those in the early months of 1923, one can see that there was a mild recrudescence of the epidemic of encephalitis in this period. In the whole year of 1921 there were but fifty-one cases signed out as encephalitis, while in 1922 there were but sixty.

On reviewing the fifty-five cases which were signed out epidemic encephalitis in the first quarter of 1923, six cases were ignored because they were chronic encephalitis, that is, the acute stage had been passed months ago. Seven cases were not considered because of insufficient evidence of encephalitis, usually on the basis of insufficient stay in the hospital to confirm diagnosis. This leaves forty-two cases which are the subject of this review.

As to age, the majority of the cases occurred in the third and fourth decades. The three incidences in which the diagnosis was made in children were all fatal. One patient was seventy-two years old.

It is significant that in only five cases was it noted that the patient had a preceding attack of influenza or any other respiratory disease. In twenty-six cases the onset was gradual while in nine it was sudden. In the majority of cases the onset was attended with neuralgic pains, which often lasted throughout the disease and into the convalescence. The most frequent sites of these pains were the back of the head, the neck, and down the arms. In twenty-four cases these neuralgic pains were specifically mentioned. Among the other localities affected were the chest, lumbar region and abdomen. Several cases mention pain in or around the orbits. Most of these neuralgic pains were radicular in type and distribution.

The most common symptoms were those referred to disturbances of the extrinsic movements of the eyes. In twenty-five of the cases it was mentioned that the patient complained of diplopia, or what is interpreted as its equivalent, blurred vision. Whether or not ocular symptoms are a *sine qua non* of epidemic encephalitis is not agreed upon. In this series of forty-two cases it was not mentioned in seven cases. Ptosis is a frequent symptom and is mentioned in ten of the cases. Strabismus or weakness of the external rectus muscle was present in eight of the cases. Difficulty in convergence and also in looking upward is frequently mentioned, but this has been found to be a very unreliable sign in encephalitis because it is difficult to determine and is often so debated. Nystagmus is mentioned in ten of the cases.

As to the intrinsic movements of the eyes, sluggish pupils were present in ten cases. In but one case were irregular pupils noted, and it is considered that in this case, the irregular pupils were independent of the epidemic encephalitis.

The various disturbances of consciousness and the psychical reactions are for convenience placed in the cortical manifestations of the disease. Insomnia, especially at the beginning of the disease, but often lasting throughout, was very frequent, being a complaint of ten or more of the patients. It is curious to note that the word lethargy was rarely used in describing the general condition of the patients, being present in only two of the histories. The general condition of the patient was described as somnolent, stuporous or apathetic in fourteen of the cases: Delirium or clouded consciousness was present in ten of the cases. In one of the cases the patient was in a comatose condition upon admission to the hospital. In one or two cases a difficulty in concentration was mentioned. A number of the cases went through many different phases of disturbances of consciousness. For instance, in one case it was described that at first the patient was sleepless, later his consciousness became slightly clouded or was somewhat slightly irrational, but still later he appeared to be in a profound sleep. In one case there was a marked euphoria.

Except for myoclonic twitchings, there was little mention of adventitious movements. Tremors of the hands were present in four cases, in one of which the whole body was said to have been tremulous. In one case there were tremors of the mouth and jaw. In two cases there were choreiform movements, with the necessity of a differential diagnosis between encephalitis and chorea. Parkinsonian facies were not prominent, being mentioned in only twelve cases, possibly because it is not apparent early, or possibly because the examiner believed he had covered it in describing the general appearance of the patient as mentioned under cortical manifestations in this paper. In nine cases unilateral facial weakness is mentioned. However this is probably as unreliable a sign as the difficulty in convergence and for the same reasons.

Dizziness was complained of in a few cases. This is interpreted by some of the earlier writers on encephalitis as irritation of the vestibular nuclei. But this was not borne out by evidence of involvement of other grey masses in that neighborhood in this series of cases and one would suggest that it is the result of the general irritation of nervous functions found in many infections rather than the specific irritation of the vestibular nuclei.

Autonomic symptoms, described at length by some writers, were not prominent. Difficulty in micturition occurred in several cases. Difficulty in swallowing and increased salivation occurred in only one case each.

No case of the forty-two showed any pyramidal signs, with the possible exception of several in which the abdominal reflexes were questionably absent.

In three cases a slight suggestion of rigidity of the neck was noted. In only one case was the neck described as rigid.

As diplopia was the most common subjective symptom, myoclonic twitchings were the most constant objective sign. They were definitely noted in twenty-three cases, most commonly in the abdomen, but also in the extremities. In several incidences myoclonic twitchings were the outstanding factor in the cases and the factor on which the diagnosis of epidemic encephalitis hinged.

Three of the cases were considered in the subacute stage and were afebrile. Of the remainder all were febrile, or more correctly speaking subfebrile, since, in the majority of the cases the temperature did not rise above 101°. Higher temperatures offered a poor prognosis for in the ten cases that reached anything over 102° seven were fatal. In two cases temperature was subnormal. In one case it was striking, reaching 96° and averaging around 97°. In this case the pulse was at the same time rapid (80-120), giving a peculiar temperature-pulse ratio. This was the only case in which the pulse went down as the temperature went up, a phenomenon that has been described. Judging by this series of forty-two cases the pulse is not outstandingly rapid in encephalitis, but is in proportion to the temperature as in other infections.

The leucocyte count averaged between 11,000 and 12,000 and increased only slightly with the other evidences of increased severity of the infection. The three cases having a count of 20,000 or more were fatal.

A slight pleocytosis was the only constant spinal fluid finding, averaging 20-30 cells. Cell count was recorded in only twenty cases, in five of which it was within normal limits. The highest count was 120 cells.

Twelve of the forty-two cases were fatal. The number and results of the postmortems were not traced. In at least two cases it is known that the postmortem verified the diagnosis. Six cases were signed out unimproved, twenty-two as improved and two as cured. In this connection it is debated among neurologists as to whether or not epidemic encephalitis is ever wholly recovered from, or if a detailed examination would not reveal some sequel or residue. It is the impression of this clinic that relapses are fairly common. No recurrences have been noted, that is, a revival of evidences of the disease after the patient has been signless and symptomless, or practically so, for some time.

Six cases were treated with Rosnow's serum with indeterminate results. One was treated with her own spinal fluid intravenously, with a satisfactory course. In the rest of the cases the treatment was symptomatic. Intramuscular injections of ether for the relief of the myoclonic twitchings were tried with no more definite results than from the subcutaneous injections of eserine for the same purpose.

Psychoanalysis, Its Theory and Technic*

By JOSEPH SMITH, M.D.,
New York,

Chief Psychiatric Clinic, Beth Israel Hospital; Associate Neurologist, Kings County Hospital; Consulting Neurologist, Jamaica Hospital.

At the present time no apology is needed for bringing up the subject of psychoanalysis for discussion before medical men. Psychoanalysis fought its way to recognition slowly, after much criticism and derision were levelled against it. To be sure, occasionally, here and there a voice is raised against the sexual theory of the neuroses, but physicians have become tolerant and inclined to take a more sober view of psychoanalytic disclosures. It is natural that a theory and method so revolutionary should have met with such opposition, for it arouses slumbering thoughts in one's own unconscious which makes meditation about such subjects a rather unpleasant occupation.

I propose to present the psychoanalytic theory of the neuroses leaving out demonstrations from personal observations, for I am sure that the views of Freud which have as a basis the combined experience of workers throughout the world are far more convincing than any isolated experiences of one's own as a contribution in this field. It is therefore a digest of facts and theory which I am about to present to you for discussion.

The cornerstone of psychoanalysis is Freud's theory of the unconscious. That there are unconscious phenomena in our mental life has been known long before Freud, but his conception of the unconscious differs from the connotation given to it by previous investigators. It is not the unconscious which results from the mere frequent repetition of activities that they in the end have become automatic, hence no longer consciously performed. The unconscious in Freud terminology is a special mental realm where are stored up memories and recollections which had to be repressed or banished from conscious thinking on account of their unpleasant character, or activities which have likewise been repressed because of their immoral or antisocial tendencies. We have to consider with Freud that certain activities in childhood, as well as certain phantasies in this period of life are being constantly censored and inhibited by those about and this repression is especially severe where the sex activities of the child are concerned, not only excitation of the genitalia and onanistic practices but the child's curiosity for sex information, his love of exhibitionism, thumb sucking and other perverse activities. Usually when the child is caught in any of these performances, the rebuke is so stern that he realizes that he has done something wrong and the whole incident is frequently repressed into the unconscious, so that a complete amnesia of the occurrence results. These earliest repressions form the deepest stratum of the unconscious and inasmuch as the effects connected with such experiences are capable in the near or remote future to give rise to a neurosis, the psychoanalytic investigation, in order to be thorough and complete, must take into account the possibility of such early experiences, and devote time to them.

In later life, during adolescent and adulthood all experiences which lacked the means of being realized or whose realization was opposed strongly by contrary motives, are also repressed into the unconscious. Observe here that such activities as are repressed are in their nature pleasant desires or activities, and that the repression is the result of antagonistic impulses, some tending to favor the expression or giving free rein to such tendencies, others to suppress them, violently if necessary. The triumph of the suppressing force does not mean any more than the fact that a temporary overwhelming by a superior force has been achieved, but the wishes nevertheless continue to exist in the unconscious, are forever striving for conscious expression, but are repeatedly being prevented from doing so by repressing tendencies which must be constantly on the watch. Such suppressed desires, however, manage to manifest themselves either in dreams, as disguised or undisguised wishes, or as symptom formations in case a neurosis results in the future. Analysis has shown that nearly all suppressions have to do with sex activities, for no other instinct has suffered so much repression. Freud singled out for his study the sexual instincts, not because of any predilection, but because in his investigations of the neurotic symptoms he was constantly confronted by sex notions, sex phantasies and sex experiences as the most obtruding material in the lives of the neurotics. Anyone who has had occasion to observe the behavior of an hysteric during a convulsion cannot be left in doubt as to the nature and meaning of this hysteric manifestation—in the feeling of languidness, tingling and faintness, often mingled with anxious expectation, in the character of the bodily movements, the feeling of relaxation and the act of crying following the convulsion there is reproduced the typical sexual experience of the first coitus. Charcot has described passionate attitudes in the hysteric which are unmistakably grossly sexual. That, also, in the traumatic neuroses, the real trauma is, not the injury sustained, but the traumatic fixation of instinct, or that the disease is the result of the uneven or unsuccessful struggle which the libido (or sex urge) has waged against the moral forces, has been abundantly proven by analysis of traumatic neuroses in civil and military life.

---

*Read before the combined meeting of the Queens County Medical Society and staff of Jamaica Hospital, June 18, 1923.

We have already stated, that analysis of neurotic patients forced upon us the conviction that their symptoms represent substitute formations for erotic wishes that could not find *expression in reality* for the reason that such desires were incompatible with the demands of cultured society. A neurosis, then, cannot arise unless such a moral conflict precedes it, the contending forces—sex demands and ego demands—finally compromise, with the result that the idea or incident suffers repression into the unconscious, but the affect belonging to it, representing as it does, a quantum of psychic energy, is transformed into motor activity or sensory innervation. According to this conception, hysterical paralysis, for example, results when the liberated energy is employed in blocking the pathway for motor innervation; or paraesthesias from the utilization of such energy to cause sensory irritation, etc. Since repression always follows psychic conflicts in neuropathic individuals, the final end-process—the symptom formation—its *raison d'être*—is entirely unknown to the patient and it can continue as a symptom only so long as it remains unconscious; for a cure results when the whole process becomes conscious.

To understand the rôle sexuality plays in the causation of the neuroses it is necessary to trace the normal sexual development in childhood and adolescent life, and the many deviations or arrests which this instinct is liable to suffer in the various stages of its development. In his *Three Contributions to the Sexual Theory,* Freud outlined his ideas concerning the development of this instinct. It would appear that the sex instinct, or rather one of its components, makes its appearance very early in infancy, that many of the activities of the child must be construed in terms of sex—if by sexual we agree to adopt Freud's broad conception of it. Viewed in this light, mouth and anus, in fact any sensitive skin area capable of giving rise to pleasurable sensations, are to be regarded as erogenous zones. These are sources of sex activities long before the genitalia become the chief instruments of such gratification. As the child develops, manifestations of the instinct become centred about the genitalia and masturbation is the result. In the further development of the individual, masturbation is relinquished for normal coitus. It is, however, possible for any of these intermediate stages of sex development to become arrested, either partially or wholly, and the result will be a fixation of the instinct which clings to life. Unnatural sex gratification and perversities take their root in these fixations. Observe also, that in connection with the development of these gross sexual instincts, there goes on a similar process of development in the higher sex expressions—I mean love. The first attachment of the child is toward his parents, with a preference toward the parent of the opposite sex, the girl clinging toward the father, the boy instinctively loving the mother, and there is abundant proof that such feelings are not as innocent as we are led to believe. Analysis of dreams of neurotics and even of normal people, show how frequently the socalled œdipus complex is an integral part of a neurosis, and that libidinous desires and phantasies toward the mother is common. No other statement of Freud has elicited so much condemnation as this one—the reason for such rejection, it appears to me, is twofold. Some people feel keenly that they themselves have had such notions in childhood, and the resistance they manifest toward this theory is transparent; secondly, the majority of mankind has so effectively outlived such infantile tendencies and fancies that they cease to be reckoned with later in life. The normal does not attract us and we are cold toward that which seems to bear no consequences. It is only the pathological which arrests our attention. Freud was compelled to introduce the consideration of the œdipus complex because analysis has shown that this pathogenic complex regularly exerted an influence on the life of the neurotic—in other words, that he never effectually outlived his earlier infantile attachments. The normal youth, at about puberty, gives up his love attachment to his mother as the sole object of his affections and transfers his sexual feelings toward an object outside of his immediate family.

Freud has also emphasized another stage of the sex development of the individual—the narcissistic stage. In this stage, which follows immediately the oroanal stage, the child finds greatest satisfaction in the admiration of his own body. When the further development is hindered by some accident, the narcissism may color the whole life of the individual. We find it especially in those selfish, selfsatisfied, egotistic individuals who exhibit so little regard for others. In the psychoses we see them exemplified in the dementia precox and paranoid groups. These patients exhibit an utter lack of libido attachment toward others, are boundlessly egoistic, selfcentred, egocentric, totally lacking in feelings of sympathy for others, in social sense and duty, are devoid of feelings of responsibility, hence are slovenly, lazy and indifferent. In connection with fixation of instinct, we must familiarize ourselves with another process known as *regression,* by which term we designate a return to an earlier stage of sex activity. A woman, for instance, may be forced to adopt masturbation as a means of sex gratification if a normal outlet is prevented either by reason of nonmarriage or rejection of illicit sexual intercourse. Though physiologically permissible in childhood period, masturbation is not the mode of sex activity of the normal adult, and regression thus becomes a return to infantile sexuality.

Having gained some insight into the nature of the unconscious, of the processes of sex development and the probability of their being arrested or fixated at any period of development, these fixations serving as points which later may manifest themselves as part symptoms of a neurosis; after having learned the meaning of repression and the nature of the repressing force, and of the process known as regression, we will turn our attention to the consideration of the psychoanalytic method.

If our theoretical considerations are correct, the cure of a neurosis will consist in removing the resistance by which the suppressing force holds the traumatic occurrence in the unconscious; by thus rendering conscious what has previously been unconscious, the incident is freed of its pathogenic effect. The aid given by the analyst consists solely in guiding the patient to the solution of his own conflicts, and unless the explanations and interpretations offered to the patient are accepted by him in the sense that the connection between his symptoms and complexes, which for a long time lay submerged in the unconscious, are fully realized and the whole process carries conviction, the patient is not cured.

Psychoanalysis makes use of the method of free association; the patient is directed to tell everything that comes to his mind without exercising any choice whatever in respect to what he reveals. Thought is thus removed from all hindrances, there is no goal, no aim, no guiding idea. Since the repressed thoughts and desires are constantly striving to become conscious, the manner of free association affords them the easiest way to achieve their purpose. They manage to reach consciousness, however, only in a distorted and disguised form, because consciousness is not ready to countenance the naked truth. Only when the patient is in a position to take up the struggle anew, which the aid and preparation of the analysis has made possible, can the battle be fought over again in the open with good chances of success.

Freud was led early to the study of dreams and he found them of the greatest value in the investigation of the neuroses. The dreams of neurotics are the keynotes to the disease, to the probing of their unconscious. Freud regards the dream as a psychic process full of meaning, the dream never concerns itself with trifling matters but with subjects of tremendous importance to the individual. The dream, as it is revealed to, and remembered by us on awakening, is the manifest content, while the ideas free association lead us to is the latent content. The dreams of the neurotic can be regarded in the same light as his other symptoms, that is, they are manifestations of censored wishes which, on account of their incompatibility with the rest of the personality, had to be repressed.

Again, the repression has to be steadily applied, since the wishes show a tenacious persistence to break through the threshold of consciousness. However, they do not succeed in becoming conscious except in a disguised and distorted form.

There are several details about dream formation and analysis which it is important to keep in mind:

1. The dream represents ideas and situations by means of pictures—a sort of visual hallucination.
2. The dream generally fuses many occurrences into one, a process spoken of as condensation.
3. A process, the reverse of the latter and known as overdetermination, occurs, in which a single element in the latent dream thoughts may be represented by several scenes in the manifest content.
4. Displacement, a process the purpose of which is so to distort the latent dream thoughts as to render them suitable for conscious apperception. This is accomplished by shifting of the accent from an important event to an unimportant, or the affect may become displaced from its proper setting and attached to an indifferent occurrence.
5. Symbolization. A little reflection will show us the close similarity between dream and neurotic symptom; the symptom is a projection outward of an inner conflict, the dream is likewise a distorted expression of a prohibited or an unrealized wish. In both instances the same mechanism operates: Inner conflict, repression, a striving to find expression which is only achieved when the ideas undergo distortion, displacement, condensation and symbolization to such an extent that the obvious meaning is unrecognizable, and thus can reach consciousness. The analytic technic aims to remove the resistances by which the ideas are prevented from becoming conscious. It lays bare the nature of the psychic conflict and thus frees the whole process of its mysterious background. The fundamental purpose of the dream is the realization of an infantile wish. This statement of Freud is not only supported by analysis of dreams but is also in agreement with a profound mass consciousness which expresses itself in the saying—"In my wildest dreams I would not have anticipated that," thus attributing to the dream a definite aim—that of bringing satisfaction to our deepest yearnings and aspirations.

Analysis of dreams is frequently difficult. The more formidable the repression is, the greater will be the distortion. Though an intelligent patient may furnish much material which would enable one to interpret the dream, it requires considerable experience and adroitness to do analysis ably. The immediate excitants of a dream are significant occurrences of the day, but analysis of the latent content reveals numerous reminiscences of the past, often exceedingly remote, reaching into childhood experiences, all the material undergoing elaboration, displacement and condensation to form the manifest dream. The motive of the dream is the realization of childhood desires and aspirations and yearnings of later life. The distortion which the dream thoughts suffer may also relate to the affect of the occurrences. It may be left out entirely or the effect may be transposed to an indifferent occurrence or personality, which may render the dream unintelligible, or the dream work may make use of symbolism to hide the meaning of the latent thoughts. Symbolism is a likeness, close or remote, which can take the place of the original.

We make use of symbols to express ideas in a concrete form and to disguise the meaning when direct connotation is inadmissible or inappropriate. Wit and humor frequently clothe themselves in symbolic expressions. Especially rich in symbolism are sex ideas and thoughts, for the reason that our social morality has placed restrictions upon uncensored sex expressions. Analytic philology has thrown much light on the origin of symbolism and the study of folklore has equally contributed toward the understanding of this strange mode of representation. There is one more process which I would like to mention before closing. The process I allude to is known as transference and the importance of the subject can be inferred from the fact that curable neuroses are known as transference neuroses, in contradistinction to those incurable mental affections in which transference does not take place. These latter are spoken of as narcissistic neuroses. Briefly, by transference we designate an ability to project the libido onto an external object. In the course of an analysis the physician soon notices that the patient becomes interested in the personality of the analyst and finally transfers to him all the feelings and sentiments, friendly and hostile alike, as if, in the patient's phantasy, the physician assumes the rôles of all those against whom these emotions were originally directed. This is what actually takes place and it serves the purpose of reconstructing anew the neurosis, by the patient's going through the various stages of it again. The physician is face to face with an acute exacerbation of the symptoms, but the sexual life of the patient being known to him, as well as the suppressions which the libido has suffered, he is able to direct the storm to a successful issue.

I am near the end of my paper. It is needless to say that I am peculiarly conscious of its imperfections and limitations. One supposed objection already stated I will try to answer. It may be said that I offered not a single clinical proof of any assertion I made. I am not, however, conscious that by the elimination of case descriptions anything has been lost of the validity of the presentation of the subject. The conclusions and theories of psychoanalysis have been arrived at from strictly clinical observation. The introduction of a few more cases would not add anything substantial to the subject but would tend rather to obscure the whole by unnecessary detail.

Aseptic Meningitis in Combating the Dementia Precox Problem

A Preliminary Report

By ROBERT S. CARROLL, M.D.,
Asheville, N. C.,
Medical Director, Highland Hospital.

BAFFLING NATURE OF DEMENTIA PRECOX.

A generation ago pulmonary tuberculosis was the dread of the internist. Certain forms of cancer, today, are the despair of the surgeon. Even so, since mental diseases have been classified, those forms which by the Kraepelinian school have been designated dementia precox, or schizophrenia under the Bleular classification, have been the *bêtes noires* of the psychiatrist. To diagnose precox has been, at best, to condemn the victim to a life of sadly reduced efficiency; even today, for the majority, it carries a life sentence of narrowed institutional existence. In vain have scientists, the best of our age, in laboratories lacking no item of perfect equipment, labored in sincerity, in detail, in effort beyond lay belief, labored to exhaustion.

CONFLICTING THEORIES.

Long since, our profession laid the ghosts of superstition, ignorant and orthodox, as to the causes of insanity. The curse of the voodoo, the baleful addling of the moonbeam, the displeasure of the Almighty, alike have given way to efforts to rationalize. Heredity has been accused of cheating the dementia precox patient, of giving him a mentality of mushroom quality which reaches its apex of ability early and early recedes.

The internal secretions, in the very seminebulosity of their real chemistry, in the intricate nature of their physiological activities—how tempting to associate the indefinite with the indefinite! I have diligently theorized and therapeuticized along the lines of perverted thyroid, disturbed parathyroid, deficient sex gland, broken hormone balance, with few results which could not be traced to improvement following general metabolic elevation and better habit formation through constructive custodial influence.

Gastrointestinal intoxication has for years claimed an important seat on the rostrum of reasonable theories. The dementia precox bacillus was almost isolated! Colons have been ablated and, without doubt, gastrointestinal hygiene, including a lowered protein intake, has appealed favorably to many practical workers. Today, focal infection has joined hands with autointoxication and thousands of sepsis breeding teeth and foul tonsils are being removed with unquestioned aid to the disease fighting forces. To these somatic theories can be added that of choroid-plexus inadequacy. This would make possible, through the reduction in choroid plexus integrity, a defective cerebrospinal fluid. Probably the most favored theory today of the majority who accept a biochemical basis for precox might be stated as the combination of autointoxication, septic focus and choroid plexus insufficiency.

But the suggestion of complexity turns us toward a confident group—the many who sit in high places and teach the psychogenetic basis of this dread disease. The pendulum has indeed swung far, in the psychic department of science, in this acceptance of the power of mind over matter. And truly great has been our understanding of complexes, transferences, sublimations, blockings and mental disorganizations generally, which result from the patient's inadequacy to meet the intricacies of civilization. Moreover, psychoanalysis has stimulated professional contact with patients, suggestive, persuasive, analytic, undreamed before in the treatment of precox. And these efforts have often been fruitful, even as have surgical, special dietetic and more direct reeducational methods. But in face of long continued physio- and psychotherapeutic efforts of rarely equipped minds, there exists today no absolute road of approach to this dire problem.

ASEPTIC MENINGITIS.

We have passed by another theory which excited some of us about ten years ago, when Lundvall, of Sweden, observed in some of the dementia precox cases under his care a leucopenia when his patient was losing ground, and a hyperleucocytosis during improvement. Many of us then recalled instances of startling remission in even quite advanced cases recovering from septic infections and showing an active leucocytosis. In 1895 Dr. Adolph Meyer had written: "Whether, indeed, the lucid intervals and rapid improvement of torpid cases after infections which produce leucocytosis (typhoid fever, tuberculosis, suppuration, and other conditions) might be due to the fresh regenerative impulse, will be a question worth examining" (1).

Dr. Bayard Holmes then wrote an article suggesting the use of nuclein in the arrest of dementia precox, and numbers of psychiatrists used Lund's solution of nucleinate and cinnamate of soda with arsenious acid injected intramuscularly to produce a plethora of leucocytes. But it was soon found that these aggressive repair cells when lacking pathogenic material to feed upon turned to the normal red cells for pabulum; and that a secondary anemia was thereby scientifically produced. Since then little has been heard of hyperleucocytosis as a therapeutic agent for the alienated.

In January of this year in a mental tilt with the problem, following the reading of Dr. Charles E. Dowman's paper, Trans-Choroidal Therapy in Neuro-Syphilis; Preliminary Report, based on the work of Mehrtens and MacArthur, the thought came of an injured choroid interfering with normal chemotaxis, and that, perchance, dementia precox might prove a food-chemico deprivation, rather than a toxic destructive process. In pursuance of this theory, and in hope of restoring choroid permeability, Dr. W. W. Young, our resident physician, removed twenty-five c. c. of laboratory normal cerebrospinal fluid by lumbar puncture, and replaced it with an equal amount of inactivated horse serum in a case of marked catatonic stupor. The symptoms of an aseptic meningitis followed. No mental change was observed. A week later a second treatment was given. The next day the patient was quite himself for the first time since his admission.

In our unfortunately all too short series of cases, the seven day interval has been most satisfactory. A minimum of two, a maximum of five injections have succeeded in producing either temporary or permanent lucidity in every dementia precox case thus treated. The temperature usually reaches a maximum of 102.5° with no untoward disturbances of pulse and respiration. Backache and headache are present for thirty-six to seventy-two hours, and nausea, sometimes vomiting, may be expected during the same period. It is common for the patient, during the height of his discomfort, to prefer to stand or lie with his back pressing against a hard surface. A slight strabismus, herpes labialis, generalized urticaria, and an anaphylactic threat with expiratory dyspnea have been observed following a few of our over sixty injections. In most cases, temperature, pulse and respiration have returned to normal within three days.

The laboratory findings are of greater interest and, we feel, most significant. The monograph of papers from the Army Neurosurgical Laboratory, issued by the Rockefeller Institute, March, 1920 (A Study of Experimental Meningitis), is an exhaustive exposition of various forms of meningitis, including those produced by foreign sera. In these experiments over twelve hundred cats were used. An excellent idea of the margin of safety can be derived from this monograph. In cats it was shown that a pleocytosis amounting to even 6,000 per c.mm. was produced by horse serum within eighteen hours following spinal injection. We have found an average cell count of 100 or more per c.mm. in fluid removed even fourteen days after an injection. The phagocytic activity of this even two thousand per cent. increase must be obvious. The presence of from one to eight per cent. of eosinophils, unique, so far as we have been able to ascertain, in any other condition of the cerebrospinal fluid, possesses a significance at present unknown to me. It is possible that the eosinophils develop in an effort to neutralize the foreign proteid contained in the serum. It is theoretically possible that the precox disordered protoplasm contains chemicals which the acidophilic eosinophils possess a power to neutralize or appropriate. We have observed that the larger percentage of eosinophils has been found in patients making the most satisfactory response.

The usual cell count in spinal fluid removed during treatment is: Mononuclear lymphocytes, 95 to 89 per cent.; true phagocytes, 4 to 6 per cent.; eosinophils, 1 to 5 per cent.; neutrophiles, 0 per cent.

Of most profound interest to us, however, are the mental reactions. Little or no change has been the rule following the first treatment. The appreciation of reality, in recent cases, has always developed by the fourth injection, usually by the third. In those with hebrephrenic or catatonic symptoms of from four to six months' duration the response has been more permanent. In chronic cases, those with precox histories dating back three to six years, the reactions have been paradoxical. One patient who had been destructive, resistive and untidy for thirty months; in whom precox symptoms had been observed for six years; who had been mute for practically one year, asked intelligent questions concerning the treatment within two hours. It was found that this girl's contact with reality increased until in thirty hours, when the artificial leucocytosis is at the peak, it would have been difficult to detect any abnormality in her conduct or conversation. With little help she disclosed the mechanism of her delusions, admitted her hallucinations, discussed them as a symptom, wondered at her helplessness in control of them. Then the slow reclouding until at the end of a week she was quite shut in. This case's reactions were largely hebephrenic.

In contrast is a young man with a four years' psychosis, diagnosed as hebrephrenic precox by Dr. Archibald Church at the Chicago Psychiatric. During the last ten months increasingly catatonic reactions alternated with stupor and periods of panic. Four spinal treatments with one week intervals produced no results. The day following his fifth he was arrayed and in his right mind. He has remained well.

Again because of our limited number of chronic patients we are unable to record the probable other forms of mental response to this treatment.

TENTATIVE THEORY.

Should we formulate our present theory as suggested by our results to date, we would state that by removing an average of twenty c. c. of cerebrospinal fluid and replacing it with an equal amount of inactivated horse serum, an aseptic meningitis, with a tremendous production of leucocytes results in all cases—far more than is necessary to rid the fluid of the irritating foreign proteid which has been introduced. This leaves an overplus of phagocytic energy in closest contact with neurone protoplasm, energy available for possible scavenger and reparative action on brain tissue, probably on choroid plexus. Through this method of approach Nature's most perfect remedy, her own reparative cells, can be actively and persistently kept in contact with previously injured brain protoplasm. Deadening and damaging toxins may thus be neutralized; and if regenerative processes within the brain are possible, the most perfect stimulation to that end is thereby provided.

Again to quote Dr. Meyer: "In comparing cells with possible degeneration in a terminal dement with those of more acute changes with leucocytosis one cannot help being impressed with the idea that the leucocytosis offers more favorable outlook, and the laws of its influence would be worth continued experimental and pathologic research" (1).

Case I.—Mr. J. C., aged twenty-three years. Tenth grade common school. Clerk in country store. Hypochondriacal ideas developed early in 1922. Became "worried about things." Sleep poor for some months. Suspicious, believed his food was poisoned; that his companions read his mind. Evinced vague auditory hallucinations. Admitted to Highland Hospital November 19, 1922. Quite inaccessible, catatonic rigidity, negativism. A catatonic stupor developed rapidly. Our first use of this method of treatment was made in this case January 15, 1923.

Thirty c. c. of clear, apparently normal spinal fluid were withdrawn and an equal amount of serum injected. During that week short periods of lucidity appeared. On January 22nd the treatment was repeated. The fluid now withdrawn, with no sign of increased pressure, was found slightly clouded and had 105 cells per c.mm. Temperature went to 102.8° and gradually decreased to normal. On January 24th the patient's father came to transfer him to a State hospital. The boy who had previously shown no insight protested that he had been very sick and was getting well; indeed quite convinced his father of the hopefulness of his condition. During the following week he read three novels and discussed them with interest.

On February 7th he received a third treatment because of the appearance of a mild depression. This was two weeks after the second, and 110 cells were still present. Following this final injection, the patient's progress physically and mentally was most gratifying. A nice sense of humor, a remarkably clear insight into his illness, a willingness to carry out the dietary and vocational routine planned for him, expressed his purpose to help himself. An out of door regimen of eight hours' work, gymnastics and play was followed for weeks without objection. The patient developed excellent skill in baseball, becoming one of the best hitters on the hospital team, and was dismissed on May 15th to return to his home with every evidence of normality. In this case we were treating a very recent psychosis and secured most gratifying results. A letter from the patient dated August 20, 1923, tells of a busy, normal summer.

Case II.—Miss N. E., aged twenty-three, had completed her freshman work in a northern university, and was considered brightest in the family, with a mind "specially keen." She was doing stenographic work in a physician's office when she became irritable. Short periods of excitement alternated with days of apathy. Delusions of unworthiness, ideas of persecution, objectless laughter, illogical repetition, emotional incoordination, confusion and hallucinations appeared. Diagnosis of hebephrenic precox made by Dr. H. Mason Smith, of Tampa. Upon her admission, January 3, 1923, marked apathy was interrupted by short periods of panic. Cyanosis of hands and feet was almost constantly apparent. Patient was disoriented as to time and place, and the days passed without interest or accomplishment.

On February 20, 1923, a lumbar puncture was done and twenty c. c. of fluid withdrawn and replaced by the same amount of horse serum. Temperature rose to 102° F., subsided in forty-eight hours. February 28th same treatment. No alteration in behavior apparent. March 7th, third injection. Cell count 110. Two per cent. of eosinophils were found in a stained cerebrospinal fluid smear. Patient became normal in conduct and remained so for eleven days, then clouded somewhat. March 22nd the fourth treatment was given, fifty-four cells being found at the end of this interval. On April 2nd the final injection was administered. One hundred and ten cells were present with six per cent. of eosinophils. It is noteworthy that the patient cooperated fully in this last treatment, recognizing then, for the first time, her need and the benefit she had received. During the two weeks following there were periods of rather normal homesickness and reasonable anxiety about family finances. Unfortunately, on April 16th, the father, younger sister and a physician relative, on their way north, visited the patient. They united in considering her so improved that further treatment would not be needed; and in the face of the gravity of the diagnosis and our statement that her mental future was still decidedly in the balance, they took her to her home in New York State. Needless to say, the transformation in this patient's mental condition which influenced the family's decision had been a remarkable one. Still later reports tell of continued gain, of plans to resume her duties October 1st.

Case III.—Mr. P. M., aged twenty-nine at the date of his admission to Highland Hospital. Salesman in a department store in Chicago; two years high school education. As a private in the engineers, was at Camp Grant four months and in France from September till June following. Was popular as a salesman and in the army. The January after his discharge, ideas of persecution, growing apprehension and auditory hallucinations developed. In May, 1920, he practically held up traffic for four hours by perching himself on the ledge of a fifth floor window in the Auditorium Hotel in Chicago, threatening to jump if molested. A fire net was held in readiness for nearly two hours while a friend was brought across the city, who from the window of the next room coaxed him back to safety. The diagnosis of hebephrenic dementia precox was made in the psychiatric department of Cook County Hospital, and on June 21, 1920, he was transferred to Highland Hospital.

For three months his interests remained most narrow and shallow. His responses were inconsequential, his apathy almost continuous. Under out of door therapy, absence of nicotine and a low protein diet he slowly emerged and six months after his admission had become quite social. His interests multiplied, though his intelligence standard never returned to the normal. For one year he did simple attendant's work in the hospital. But during the early summer of 1922 his freedom was necessarily restricted following aggressive attempts at assault on two negro maids and a nurse. Then delusions, bizarre and mixed, appeared, slowly and, to all appearances, irrevocably intensifying, until all responses disappeared and he lay day after day in a state of unrelaxed tension. Dr. Hohman, of Phipps Clinic, seeing him, spoke of the case as specially hopeless, noting particularly the constant tension of the flexor muscles of the neck with the persistently semielevated head.

February 16, 1923, the treatment outlined above was administered. Cerebrospinal fluid showed five cells to the c.mm. Treatment repeated February 27th. This was followed by the most active reaction we had yet observed. Rectal temperature went to 104° F. Herpes labialis appeared. A slight convergent strabismus was present for four hours. Spinal fluid count had increased from five to 120 cells. Mentality uninfluenced. On March 12th, same treatment. Patient had been somewhat less stuporous during the preceding week. Eosinophils one half of one per cent. March 24th the fourth treatment. Two per cent. of eosinophils found in the 110 cells present. Patient had been more restless and had shown a few short periods of excitement in which his conduct quite resembled similar prolonged periods of a year before.

On March 31st the patient asked for his tooth brush, and has been mentally alert and rational since. Later, as he spoke of being "somewhat depressed," another and final treatment was given April 9th, cell count 105, eosinophils four per cent. Patient's behavior and mentality have since remained at normal levels.

Case IV.—Miss E. was a sensitive daughter from a home of refinement. She finished the first year in a Western university. Patient was twenty at the time of her mother's death. This loss was followed by some months of depression, when she was self-pitying, almost unsocial, and from which improvement was slow. At twenty-three she rapidly became apathetic, semimute and mildly catatonic. Following a dilatation and curettage under etherization and extensive pleuraglandular therapy, a quite satisfactory remission occurred and for eighteen months she was able to live at home, with the care of a special nurse. In the fall of 1919 hypochondriacal ideas were again expressed. These steadily deepened, while obstinacy and fears of contact developed. She was twenty-six upon her admission to Highland Hospital in April, 1920. Cyanosis of the hands was then noted. Hands and feet were damp, even wet, with perspiration. Dermagraphism was marked. Quite constant facial contortions, especially contractions of the frontooccipitalis. Patient was semimute, with no ray of insight. Sleep had been regular for some months. In view of the unsatisfactory nature of the symptoms the case was referred to Phipps Clinic, where she spent four weeks under observation. Returned to Highland Hospital June, 1920. Since then periods of catatonic excitement have alternated with weeks of hebephrenic apathy. For a year patient has been destructive, refusing her bed, has been tubefed for weeks, untidy in her habits, and mute save for profane outbreaks when excited.

February 9, 1923, the first treatment was given. Temperature went to 101° F. and for twenty-four hours the patient complained quite constantly of headache and backache. Her first rational utterance in months occurred two hours after the initial serum injection, when she turned to the attending nurse and asked, "Who gave me that treatment?" "Dr. Young," the nurse replied. "Why didn't Dr. Carroll give it?" she then asked. In explanation the patient had never seen Dr. Young until that morning.

On February 16th the second injection was given. Within twelve hours a nurse who had known Miss E. ever since her admission, after ten minutes' talk with her came out of the room as though she had been on holy ground and repeated, "I've seen a miracle." The very interesting feature in this case is that for twenty-four hours following the injection she showed the reactions of any wellbred society girl. She who had shut herself utterly away from all human contact, craved the association of others, clung to the doctor's hand and enticed him to stay by keeping up an adroit series of questions about his professional and personal interests; expressed discriminating affection for the nurses; was her beautiful, best, charming self. Then the fateful recession of this winsome personality, day by day, into the limbo of insanity. During her forty-eight hours of normalcy the psychoanalyst would have delighted in her eager cooperation in seeking out the underlying psychic factors. The family's "business had failed." She was a "pauper" and one of her family did not "take charity." She could not accept bed and board or attention from strangers. A genetic psychic element was found in her authenticated statement that her only real love had been for a married man. He being unattainable, what was "left to love"? Most rationally thus would she face and explain her complexes. A perfect opportunity was thereby afforded psychically to untie the Gordian knot. Following the third injection in which results were even more satisfactory and prolonged, further treatment was discontinued because of a sister's fear of dangerous complications. For two months, however, the patient ate normally, and, while deluded, talked freely and was entirely tidy in her habit.

Case V.—Mr. A. V. S., born 1893, completed two years in high school. Did work as chainman in an engineering corps for three years, then clerked in the cloak department of his father's general store for eight years. Was top sergeant during nearly two years in France. Drank some. Was fond of outdoor life. Was neat and dressed well, till the fall of 1918, when his habits altered. He drank heavily though irregularly, believed he had "a disease." Became inconsistent, remote and distant and increasingly careless in all his habits. In March, 1922, following a left herniotomy, he lost rapidly. In June had an unreasonable tantrum, with screaming. Began muttering and talked to himself almost constantly. He would count the months over and over again and repeat monotonously, "If I had only followed father, this never would have happened." He insisted he could never recover from the herniotomy though the result had been perfect. Restless habits were conspicuous. He bolted his food, left his trousers unbuttoned, refused to bathe, and at this time said he heard voices. He emitted hoarse throat sounds; many obscene expressions; had absolutely no insight; insisted that he should not be in a place for insane patients.

During his stay at Phipps Clinic some improvement in conduct was noted. Occasionally, however, he became very excited, yelling at the top of his voice. His best friends were unable to make contact with him during their visits. He would talk backwards. Stereotopy was marked. His affect was definitely incongruous, as he would laugh loudly and curse his girl friend at the same time. The final note in his Johns Hopkins abstract reads, "He became gradually more and more careless in his appearance, and therapeutic efforts had no effect."

He was referred to Highland Hospital, entering February 25, 1923. A strict reeducational regimen with low proteid diet and discontinuance of nicotine, and the advantage of many hours daily out of doors with a trained attendant, failed to alter the picture. On May 2, 1923, the treatment outlined above was instituted. The most marked reactions we have seen in our series occurred in this case. For twenty-four hours following the first serum injection, a giant urticaria invaded most of the skin surfaces. This responded within twenty-four hours to saline purgation and the administration of alkalines.

The second treatment was given May 29th. The patient was absolutely unreasonable at the time, shouting and screaming, practically incoherent. The spinal fluid count was 48 and the smear showed three per cent. of eosinophils, with many large vacuolated mononuclears and some containing pigment granules. For three hours after the treatment the patient was quiet, then became wildly delirious, absolutely inaccessible. Isolated convulsive movements developed with a marked bronchial spasm, an urticarial rash and an acute enlargement of the thyroid, indeed a smooth muscle tetany, which disappeared almost like magic under hypodermic injections of ten m. of one to one thousand adrenalin solution. Following this he slept quietly all night. Awakened the morning of the thirtieth, mentally normal and physically comfortable, and asked interestedly for breakfast. For four weeks a moderate temperature, irregular, with a perceptible weakening of the right external rectus, complicated his recovery. Indeed on June 9th he began vomiting; and in the presence of pressure symptoms he was given 100 c. c. of hypertonic salt solution intravenously, followed by prompt clearing, though temperature persisted between normal and 100° F. for three weeks longer. On June 29th spinal fluid was clear, chiefly small mononuclears, fifty cells to the c.mm., no pathogenic organisms, one per cent. eosinophils. The patient thus described his experience, "That second shot certainly straightened out my wits. Back of that it all seems a dream. I don't know today what made me do those fool things. I know now I have been very sick. I did not realize it at the time. That second shot certainly did the business."

On September 1st this patient was dismissed. Since May 30th he has been an absolutely different man, courteous, clean mouthed, considerate, a thoroughly good sport in his active out of door work.

In summarizing these cases, we find sudden and lasting betterment in one, gradual and satisfactory improvement in two with psychoses of recent date; a more delayed but apparently sudden reaction in the third case of longer standing; and in the most chronic one a remarkably prompt reaction, in which the normal was attained in a few hours, soon to fade slowly. We note, too, that in our work the more satisfactory the progress has been associated with a marked increase of cerebrospinal fluid eosinophils.

Naturally the tendency to hopeless chronicity commonly resulting in dementia precox focussed our serum therapy on this type of psychosis. It is possible that other fields of usefulness are fallow. Agitated depressions, the various forms of manic depressive disturbance, "idiopathic" epilepsy, the amentias, and most improbably the early paranoia types. Who shall say what may be the possibilities of benefit through this most direct means of biochemical attack? Extensive laboratory experiments on lower animals have demonstrated the harmlessness of aseptic meningitis of far more intense grade than that here recommended. Anaphylactic reactions occasionally may occur which will render tolerance tests a wise preliminary, though these reactions have responded promptly and favorably to hypodermic injections of one to one thousand adrenalin repeated every two or three hours if needed. Dangerous secondary inflammatory reactions will probably follow unwise subsequent serum injections when the spinal fluid remains overburdened with the toxic detritus of former treatments.

While theoretically the treatment is sound, I recognize how futile it all may prove. This list of cases is presumptuously small. But at the present time sixteen cases, unfortunately most of them of long standing and badly damaged, are under treatment at the Byberry division of the Philadelphia General Hospital, under the personal supervision of the medical director, Dr. Everett S. Barr. The reports of these and of cases now under treatment at Highland Hospital will be embodied in a subsequent paper.

Public institutions fairly groan under the increasing burden of morally and mentally moldering dementia precox patients—tens upon tens of thousands! If early diagnosis and prompt treatment as outlined in the first case can save twenty per cent., ten per cent., yes, even one in a hundred, our therapy will have advanced and the burden of human suffering be in so far lightened.

More efficiently stimulating agents in the production of cell repair, in the neutralization of cell damaging intoxications, will probably be found. Modifications in dosage and treatment-intervals will undoubtedly be more perfectly adjusted to the need of the individual case. But no one who has seen the apparently crushed and distorted mind rise and shake aside the mountain weight of disintegrating schizophrenic symptoms as though they were wraiths of vapor and come again, even for a day, into its mental own, can doubt for a moment the tremendous possibilities enfolded in this new method of therapy.

Remarks on Myotonia Apropos of a Case of Paramyotonia, Limited to the Orbicularis Palpebrarum*

By ALFRED GORDON, M.D.,

Philadelphia.

Myotonia or tonic spasm of the muscles presents several varieties with regard to individual characteristics of the spasm, to its distribution and to the mode of onset. It may be congenital, such as the classical Thomsen's disease, it may be acquired (myotonia acquisita), it may be symptomatic in association with other diseases of the nervous system, such as for example paralysis agitans. It may be associated with progressive muscular atrophy (myotonia atrophica) or myasthenia gravis. The chief characteristics of myotonia congenita consist of muscular contraction and fixation upon an attempt to execute some movement. This contraction is more or less prolonged. The relaxation of the muscles is gradual. Once the muscles are relaxed the patient may accomplish his intended act, but any change in the character or in the rhythm of the intended movements, such as a sharp turn or increased speed, etc., may bring on a recurrence of the myotonic contraction. It is evident that voluntary muscular action is delayed.

In contrast with this, a reflex excitation of the same muscles will produce an abnormally increased response. Another characteristic feature of the disease is the mechanical and electrical excitabilities. A tap of the tendon is likely to produce persistent localized muscular swelling. The galvanic current produces prolonged sluggish contractions with either pole and, if the electrical application is prolonged or else a strong stabile galvanic current is maintained, tetanic contractions will be observed at the closure of the anode or of the cathode. Erb also observed under these circumstances wavelike muscular movements from the cathode to the anode. A strong faradic current produces undulatory contractions in the muscles. Another characteristic point of the affection under discussion is that repeated mechanical or electrical stimulation of the muscles decreases and finally exhausts the myotonic reaction. The last characteristic feature consists of a hypertrophy of the involved musculature and of its persistence.

As described above there are several varieties of myotonia. Among them there is one which presently deserves mention, viz, paramyotonia. It is a form of myotonia in which the symptoms deviate from the classical description, of which Thomsen's disease is the type. Like the latter it may be congenital, but like myotonia acquisita there may be a paramyotonia, acquired after birth. The characteristics of paramyotonia lies in two chief abnormalities, which justly or unjustly compelled Eulenberg, Delprat, v. Sölder, Senator, Martins, and Hansenmann to isolate it and separate it from the classical myotonia. They are: The muscular spasm is brought on not by voluntary movements (like in myotonia) but by exposure to cold and even to mild cold. The muscular tonicity lasts a long time, even hours. In Case II. of J. Rosette's series (1) the myotonic reaction of some of the affected muscles was evident only after chilling them. In the fifth case of the same author, the myotonic reaction was exaggerated in cold weather, but also by a general indisposition, coryza or by an oncoming menstrual flow. In some cases published under the title paramyotonia the classical myotonic reaction could not be obtained. These few examples merely prove that the classical myotonia may not always present all the typical symptoms in their entirety, that there may be encountered variations in the number and in the degree of intensity of the same manifestations, also that the symptoms may vary in different persons and that they may be different in the same person under different circumstances.

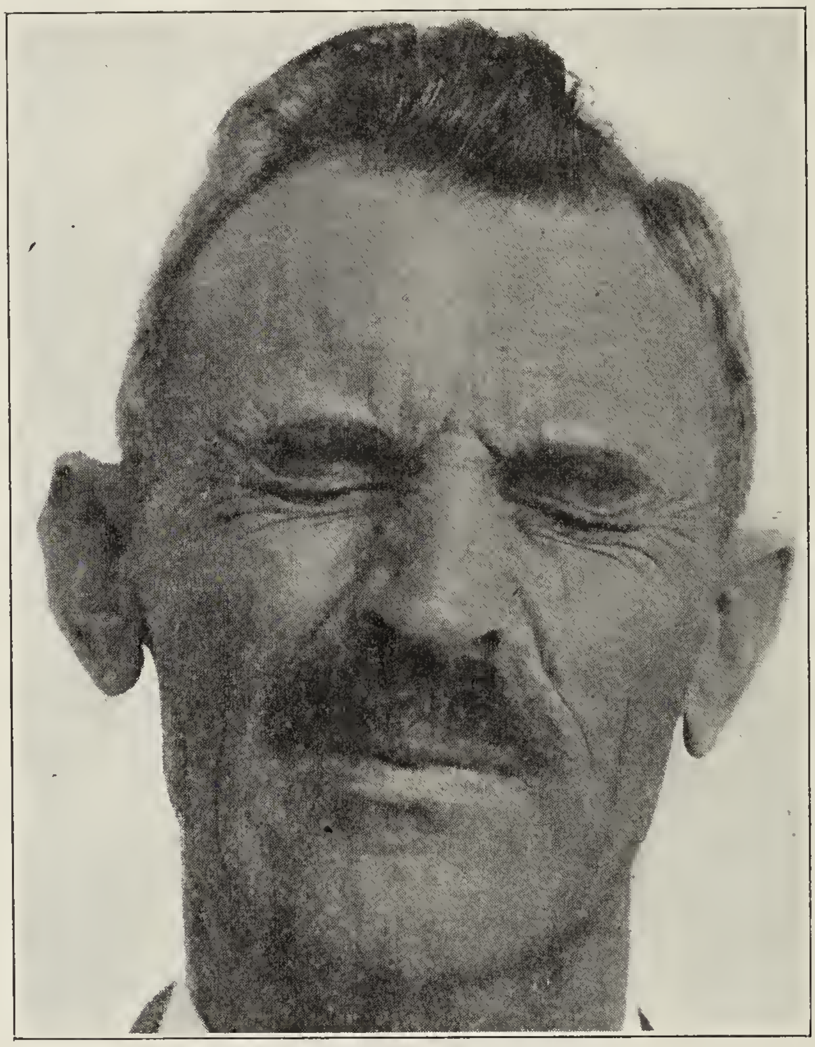

Fig. 1.—Patient during spasm.

In the following case deviations from the classical type will be observed in the original etiology, in the causative factors immediately preceding each attack, in the localization, in the duration, in the mode of relaxation of the affected muscles, finally in the electrical response. Whether the affection could be labeled myotonia acquisita or paramyotonia it is immaterial, but the outstanding feature is an intermittent tonic contraction of certain muscles. In view of the absence of the Erb's formula so characteristic of Thomsen's disease, and because of the absence of a muscular relaxation, the case would more properly belong to the category of paramyotonic group.

---

*Read and the patient exhibited at a meeting of the Philadelphia Neurological Society, November 24, 1922.

Case—H. P., male, aged fifty-two years, painter for thirty-two years, after undergoing unusual mental stress and anxiety of a domestic character, developed several months previously a spasm of his eyelids consisting of a sudden involuntary closure. At first it occurred only exceptionally, but later more frequently. The spasm involved at first not only the eyelids but also the muscles of the forehead. To use his own expression, "they would all become extremely stiff." The attitude of the facial muscles during an attack reminds one of a condition when a burning or an acid substance or a vapor or gas suddenly irritates our conjunctivæ. There is at that time a strong wrinkling of all the muscles surrounding the base of the nose as if we wished to squeeze out the irritating substance from the eyes. This condition would last many minutes even as long as ten or fifteen at each attack. The so-called tightness of other muscles would leave him first, but the closure of the eyelids would remain much longer. No effort on his part would help to open the eyes: Raising his head, trying to look up from the angles of the orbits—would not in the least degree enable him to remedy the situation during the attack. The closure of the eyes is so firm and the orbicularis palpebrarum is so rigid that no effort on the part of another person would succeed in raising the eyelids. Gradually the patient learned how to shorten each attack. He observed that blowing his nose or else turning his head abruptly for the period of seeing the object of a sudden stimulation or a noise which happened to occur near him, such as a calling out loudly by another person, would enable him to open his eyes and then he would do it promptly without the least difficulty. As to immediate exciting causes of individual attacks, he was unable to give much information with the exception of a suddenly appearing artificial light, which would promptly bring on a spasm. The onset of each spasm is sudden and the termination is also brief, although not sudden.

Mechanical stimulation of the eyelids, such as percussion or a quick tap, produces a prompt contraction and a rapid relaxation of the muscles. The same rapidity of response and disappearance of it is observed also in all the muscles which originally participated in the spasm, namely in the musculature around the base of the nose, although presently the latter no more contract during the closure of the eyelids. When this mechanical reaction is compared with that of all other muscles of the face or of the body in general, the difference is striking in that the response in the involved muscles is decidedly quicker and more pronounced. Over any other part of the body the muscular reaction is normal. The electrical test with galvanism and faradism at no time gave a myotonic reaction: there was no wavelike contraction seen; there was no tetanic contraction at the anodal or cathodal closing and there was no anodal opening contracture. The faradic current did not produce undulatory contractions which are habitually observed in myotonia congenita. In this case both currents produced an unusually prompt response and a rapid relaxation of the muscles. This was particularly manifest when a comparison was made with similar manipulations of all the other muscles of the face.

Further examination revealed preservation of mobility and of all sensibilities in the affected area as well as over the rest of the body. The station and gait were normal. The patellar tendon reflexes were markedly exaggerated, but there was no other abnormal tendon or cutaneous reflex. Ataxia was absent in the upper or lower extremities. The sphincters were intact. The pupils reacted to light and accommodation. The eye grounds were intact. The eye muscles were normal. All other cranial nerves were not involved. The mental faculties were intact. There was no suspicion of a neurotic makeup.

The patient's previous history was entirely negative. He never used alcoholic beverages. He smoked moderately. Although he has been a painter for thirty-two years, he never showed symptoms of saturnine encephalopathy or physical signs of lead intoxication. The urine was free from lead. Whether the continuous mental anxiety and worry predisposed him to the present functional disorder it is difficult to say definitely.

Presently there was some improvement in his condition in that the myotonia is confined only to the muscles of the eyelids. He was placed on frequent doses of strychnine for a period of three weeks with the result that the spasm of the other muscles than of those of the eyelids had disappeared. Biological tests were all negative.

The case is interesting from several points of view: While it belongs to the group of myotonia, inasmuch as the muscular spasm is essentially tonic in character, the contractions are only intermittent, the onset is sudden, and mechanical irritability of the affected muscles is increased. Nevertheless it differs from the classical myotonia congenita in that Erb's myotonic reaction is absent, and that the muscular relaxation after an attack is rapid instead of being slow. Another point of interest lies in the localization of the affection. In cases of myotonia and of paramyotonia recorded in the literature at my disposal, the muscles of the eyes have been only exceptionally found involved, but always in association with other gross muscles of the body. In the present case apparently only the muscles surrounding the orbital cavities were affected, while the rest of the bodily musculature was totally free from spasms during many months of the disorder. The case is apparently unique from this viewpoint. It presents an example of an additional variety of myotonia. Although it differs from the other forms enumerated, above, nevertheless it belongs to the same great group. All varieties may differ in details as to the onset, mode of termination, exciting cause, mechanical reactions. The essential characteristic feature, however, namely the tonic spasmodic contraction intermittently occurring is invariably present in all forms of myotonia.

The pathogenesis of the affection is still obscure. In the congenital form, especially in cases associated with muscular atrophy, the conjecture may be that one deals here with an inherited abnormality of muscular structure or function, or as Rosette (*loc. cit.*) suggests, with an inherited factor which exerts an obnoxious influence on the neuromuscular system: in one series of cases this factor will produce myotonia with atrophy (2, 3, and 4), in other cases only myotonia and the musculature is spared; in still others myotonia with involvement of cerebral structures, such as in cases of neoplasms of the brain (5). While such a conception of myotonia is logically applicable to its congenital form, the acquired or temporary varieties which occur in middle age such as in the present case, may not readily find their explanation from it. Schiefferdecker has suggested a distinct disorder of the sarcoplasm and of the muscle fibrils. In this connection one may recall J. R. Hunt's view concerning the two systems of motility, namely; the kinetic and static. He also believes that the motor nerve endings are beneath the sarcoplasm and therefore in direct relation with the contractile content of the muscle fibre. The investigations of Dogiel, Huber, and Crevetin have shown the existence of nerve endings of a sensory character in relation to the muscle fibre which are situated outside the sarcolemma, on the outer side of the muscle fibre, in the tendon as well as in the intermuscular connective tissue. Such a conception of a kinesthetic component of muscle sensibility is applicable to the present case especially in view of a prolonged exposure to a mineral poison, such as lead, during a period of thirty-two years. It is possible that the mental state of the patient, coupled with sleepless nights (see above) and maintained during a period of many months, may have predisposed him to an attack of the lead poison and thus rendered him more susceptible to develop a neuromuscular disorder which illustrates Hunt's view that the kinesthetic system is the sensory component underlying "the twitch," the contractile tonus and reflexes of movement.

Another view on the pathogenesis of myotonia is that of Westphal (6) who considers the affection as a congenital anomaly of muscular tonicity. Seeligmüller believes that this is due to a congenital lesion of the motor tract. Finally another group of authors (Bernhardt, Strümpell, Ballet, and Marie, as well as Dejerine and Sottas) consider the disease a primary myopathy of congenital origin. Moebius (7) also admits this interpretation but believes that we are dealing with a systemic affection of the muscles depending upon the nervous system; in his judgment the disease belongs to the group of neuroses. Dejerine and Sottas (8) found histological changes in the muscles, namely hypertrophy of muscular fibres, also proliferation of the nuclei and formation of vacuoles in the hypertrophied fibres. Whichever of the pathogenetic explanations we adopt, in the present case the unsolved element will remain as such with regard to the exclusive localization of the disorder in the muscles of the orbit. Further investigations are necessary in that direction.

I wish to acknowledge my indebtedness to Dr. W. Swindells for the privilege of studying the case.

Psychology as a Factor in the Practice of Medicine*

By HOWARD W. POTTER, M.D.,
Thiells, N. Y.,
Clinical Director, Letchworth Village.

The practice of medicine is pursued in three ways; many treat symptoms, many treat disease, and a few treat the patient as well as his symptoms and disease. It is the latter consideration which is within the scope of this paper. By the phrase treat the patient himself it is not intended to infer that his disease or symptoms can be slighted but that in addition it is essential to consider the patient as a person with powers of thinking, feeling, and acting and not simply as a spinal cord animal prone to a variety of pathological somatic states. In order to treat the patient as well as his disease it is essential to review a few fundamental principles of psychology.

"Much confusion has arisen in the language that deals with mental phenomena. In the first place the term psychology is often given, by implication, many mysterious and confusing meanings. Briefly, psychology is only a sort of physiology. It deals with human behavior, with the response of man, the wise animal, *homo sapiens,* to his environment. Just as physiology deals with the reactions of his separate organs and groups of organs to their extrinsic and intrinsic environment, so psychology deals with the response to environment of man as a whole" (1).

Personally, I am inclined to believe that it is the general neglect of psychology in medicine that is partially responsible for various cults, occult and otherwise, of a pseudomedical nature. It is because the patient does not get satisfaction from the medical practitioner, that in many cases determines his visit to the osteopath, chiropractor, or other tyro.

---

*Read at the March, 1923, meeting of the Ramapo Clinical Society.

"Among the most frequent and most commonly misunderstood results of a poor adjustment of man to his environment is the condition we call nervousness. Nervousness is not a disease of the nerves or the brain or any other part of the body. It is not autointoxication. It is not weakness of the nerves or exhaustion or fatigue nor is it a perquisite of the idle rich" (1). Above all, it is not a disease but a symptom having its origin in a physical or mental maladjustment.

Every patient complaining of nervousness or vague ill defined complaints, aches, or pains deserves a most thorough examination, physical and mental. The chief point to bear in mind is that if an exhaustive study of the physical state discloses nothing pathological, it is a mistake to conclude there is nothing wrong with the patient. If the patient had nothing wrong with himself he would not have visited the doctor. A headache may be caused by a chronic toxemia, it may also be due to a mother in law. One is just as likely to have dyspepsia from a nagging wife or husband, as from a gastric ulcer. "Human behavior is a fact and in behaving the whole individual is involved with all his mechanisms and every organ is liable to be called to duty for the special reaction. One patient may have as an indication of emotional distress palpitation, another, asthma; one may vomit, another may faint. Even in cases where there is actual organic disease present the disability of the patient may be disproportionate to the organic involvement, the patient seems to refuse to get well although everything seems to favor recovery" (1). It is well then for the physician to search for the proverbial Ethiopian in the woodpile, to scrutinize the situation and to see whether there may not be a subtle gain from the invalidism. It may then be found that the sickness is a powerful weapon or a useful crutch.

To understand how such reactions come about we must realize that in our evolutionary process we have inherited certain patterns of mental reactions on which, in our primitive state, our very life and existence depended. With the complexities and restrictions of civilization these instinctive reactions must be constantly curbed and thwarted, naturally they are especially prone to be disposed to abnormal deviations. We have an excellent analogy to such a state on the anatomical side of our makeup in the case of the appendix. These mental reactions are instincts and emotions. For our purposes in this paper I shall mention only the instinct of self preservation consisting of flight and fight and its corresponding emotions of fear and rage. It is well to point out that in man this instinct or rather its emotions of fear and rage can be actuated by abstract thinking as well as by concrete situations. Thus once there has been a particularly distressing situation engendering fear or rage, the fear or rage may be tripped, as it were, at any time by thinking back to the situation itself or by encountering some other situation of a neutral sort, which happens to be mentally associated with the original episode. The occurrence of hysterical attacks in conjunction with an inconsequential situation aptly illustrates this point.

A second psychological principle is the wish to avoid or negate some unpleasant situation without the ignominy of being a slacker in both the eyes of the public and ourselves. This evasive process is frequently accomplished by using a physical complaint as an alibi or excuse.

A third psychological principle is an inherent deside for sympathy and attention, both of which may be promoted or appeased by having some physical complaint.

A fourth concept is the psychology of pain. Pain is a relative matter. What is pain to one individual may be only an unpleasant sensation to another. Common body and visceral sensations may amount to unpleasant feelings or actual pain in some persons. Pain is dependent upon the stimulation of the nerve end-organs and the interpretation of the sensations thus produced by the individual.

Fifth, it is a recognized psychological fact that the more attention that is given to anything the more important it becomes in the eyes of that person. Again, it is not an uncommon psychological trick that if we look hard enough for a thing and believe that it is there we are very apt to find it or think we have found it, which amounts to the same thing.

Last, it should be made clear that these few psychic reactions are present in all of us subject to individual variations. They may be present to a pathological extent without physical cause. They may be released, so to speak, by a lowering of the physical reserve as a result of disease, chronic infections, toxemias, and other conditions. Finally, once set in motion, they attain a certain momentum, and everyday that goes by in which they are fed and appeased, or in some way continue to be an asset from the patient's viewpoint, just so much nearer will the patient be to a professional invalidism and just so much more remote will be the patient's chance of recovery from his or her neurosis.

Let us see what are the facts which demonstrate that emotions and feelings can cause changes in organic physiological activity. In the first place we have the brain with its various associated centres, we have efferent and afferent nerves composing the white matter of the spinal cord, and we have the sympathetic and vagotonic nervous system supplying all smooth and cardiac muscle and glandular structures.

Beginning centrally there is some evidence pointing to an anatomical seat of the emotions. Witness the senseless laughter, crying, anger, and silly tenderness of the cerebral arteriosclerotic; also the lack of emotional tone in the Parkinsonian case, or even the period of excitement or laughter of ether anesthesia.

Cannon has demonstrated on dogs and cats that fear and rage produce changes in the gastric and salivary secretion, sugar metabolism, coagulation of the blood, the action of the musculature of the gastrointestinal, cardiovascular, and genitourinary systems through sympathetic nerve influences (2).

Practically what does this mean. How may the general practitioner utilize this material, in what form in other words, since it cannot be made into a pill or dissolved in a solution, can it be administered to his patients. To begin with one must familiarize himself with the six psychological principles as outlined above and bear in mind that emotional forces are capable of producing important functional organic changes.

Second, keep an open mind toward every patient that is nervous. Do not conclude that there is nothing wrong with him or her if no organic changes are found. Bear in mind that their complaints are real to them even though they might not be real to you. After a thorough survey of the physical side assure them there is nothing wrong organically and under no circumstance use the term imagination. This term is bound to foster resentment and antagonism and gets neither the patient nor the physician anywhere. Under such a condition encourage the patient not to be alarmed over his symptoms by showing him how they point to nothing serious, and tell him the less attention he gives to them, the greater the effort he makes to ignore them, the sooner they will disappear.

Third, scrupulously avoid arousing fear or apprehension in any patient.

Fourth, do not offer theoretical explanations for their symptoms, if you cannot find a definite organic pathology. Such explanations are taken and enlarged on by the patient and frequently do more harm than good.

Fifth, promote optimism and give plenty of encouragement not only to the nervous patient, but to every patient under your care.

Sixth, if his nervousness is serving as an alibi to avoid some unpleasant situation, or if it serves as a weapon or a crutch, secure for the patient a more rational point of view, encourage him to face situations as they are, and do what is possible to remedy or palliate the unpleasant situation itself.

Seventh, if there is an element of an unhealthy demand for sympathy and attention, a frank talk followed by judicious neglect from all who come in contact with the patient, is surprisingly beneficial. Remember, above all, that suggestion is a powerful influence either in producing and perpetuating a state of professional invalidism or in furthering and hastening recovery.

"There is a mental side to every illness and the patient is a thinking feeling being as well as a collection of tissues, organs, systems, juices, etc. The bodily and mental effect of such emotions as dread, courage, hope, despair, are neither negligible nor infrequent" (1).

The Physiological Diagnostic Dream

By E. GROESBEECK MITCHELL, M.D.,

Boston, Mass.

Amid the vast investigation concerning the wish-fulfillment dream and the dream based on the fear instinct, there remains a type of dream which has largely escaped notice and to which the subject matter of this paper will be strictly confined. This form of dream may, indeed, be filled with highly symbolical imagery. Doubtless the followers of Freud will find much in the dreams cited below. In this type of dream, to which the writer refers as the physiological diagnostic dream, if there is sex symbolism that is a secondary matter, an upheaval from the limbo of the subconscious permitted by a disturbed metabolism.

I believe that in this type of dream the beginning lesions are producing pain or sensation so slight that it remains unnoticed during the distractions of the day. In sleep its stimulus produces a dream whose content corresponds absolutely to the type of sensation and to the location of the physical trouble. The forms in the dream may possibly be determined by the libido, although I believe them to correspond as a rule to the fear of a thing whose painful effect would resemble the bodily stimulus as a burning pain producing a dream of fire. Psychoanalyzing these cases, however, seems useless, as the dreams disappear with the physical troubles.

A characteristic of these dreams seems to be that they are repeated, and in only one of the cases is there any variation of the images. In this case the variation corresponds with the increase of the local disease showing a consecutive approach and increase in intensity, constituting a definite warning.

Case I.—Mrs. B., thirty-eight years old, well nourished, of rather phlegmatic type. She "did not feel well" but could not say just why, except that she felt vaguely "nervous" and "for almost a year" had been troubled by a repeated dream. She seemed to see a woman who held a lighted candle toward her left leg. At first the woman did not burn her but, at the time she consulted me, the woman had come close and did seem to burn her. The woman was always the same, resembling a nurse but no one that she knew. The dream was now repeated "every three or four nights" for several weeks and she thought she needed psychoanalysis. On being asked if she had any pain, she said that of late she "had begun to have a little pain in the left shin."

There was not much pain on deep pressure but vibration of the heel produced sharp pain in the leg. I told her she had better have an x ray and consult a surgeon, that I thought there was inflammation about the bone. She was going to New York and did not follow advice. She apparently was displeased that I did not think the trouble was with her mind. I was later informed that there had developed an osteomyelitis of the left tibia and she had been operated upon.

Case II.—Mrs. H., a frail woman of twenty-six, three healthy children. Although physically weak, was very sensible, not at all hysterical, did her own housework although she was not fit to do it. She was not a complainer but very patient. She had for several years dreamed that she was being chased for a long distance by an unknown man and would awake breathing rapidly, trembling and with tachycardia but not frightened. "I would turn over and go to sleep again."

She had once, with some other girls, been chased by a drunkard "but we just ran around the corner and I never am afraid to go out at night." Association test showed a normal mind.

She was much underweight, reflexes somewhat exaggerated, had had an appendectomy and right ovariotomy three years before, had at time a fibrous left ovary and many adhesions which gave her much pain. A later operation for the adhesions showed a fibrous band from the appendix stump to a point in the iliac fossa. The band was the size of a little finger and dragged the cecum into the pelvis.

She had intermittently coarse irregular tremors which were not intention tremors but seemed to depend largely on fatigue and sometimes caused her to drop what she was carrying. She had had these since fifteen or sixteen years of age, also sudden feeling of weakness and fainting spells, which were real and not hysterical, although she had been so called by two physicians. Tachycardias would come on without warning, usually with the tremor, and last for an hour or so, the heart would run from 90 to 100 and with irregular rhythm. Her blood pressure was variable, never over 106 and often dropping suddenly to 80 or 90 systolic. This patient being in my house, I could watch her closely. These low pressures would last for a few hours and suddenly cease. She told me the muscles of her arms felt stiff when the tremor was bad and that her wrists would feel as if a string were tied around them. Every time she said that, the pressure registered below 90 systolic.

Believing her to be deficient in parathyroid I put her on one-tenth grain three times a day. By the end of the third week the tremor and tachycardia had disappeared and with them the dream which for some weeks had been of almost nightly occurrence. As the pressure did not rise over 110, adrenal and ovarian extracts were added with decided improvement in the average pressure and the fainting. She stayed on glandular therapy for a year, during which the dream did not recur. Stopping glandular therapy for a few months, both physical symptoms and dream recurred and again disappeared under glandular therapy.

Two years later she again had fainting but this was from weakness and pain, from adhesions and the left ovary, and she died following an operation after I had left Washington.

In this case the tachycardia, tremor, dyspnea all corresponded to the physical condition following fright and flight and the dream was the subconscious justification and selfexplanation of the bodily sensation.

CASE III.—A negro, aged forty, came into the medical clinic at Freedman's Hospital, complaining that he was continually dreaming about a rat. The intern referred him to the neurological clinic. The man was underweight. He did not appear nervous. He complained that he was troubled because he kept dreaming about a rat which gnawed him over the right hypogastrium. It never seemed to come from anywhere in particular or do anything else. "It was just here, a-gnawing, and then I wake up."

Questioning elicited the following history: Three years previously he had an attack termed by his physician "acute indigestion, followed by sour stomach." Not doing as well as he thought he should under medical treatment, and reading some article in a health magazine, he stopped treatment and followed the dietary rules of the article mentioned. He drank a cup of hot water and a quart of hot milk in the morning, drank about a quart of water during the day and about 6:30 ate a dinner of meat (no pork) or fish, potatoes and green vegetables and whole wheat bread and a light dessert. No tea, coffee, alcohol, cocoa or tobacco. He retired about eight as he rose early. About nine or ten he often awoke, dreaming the rat was gnawing him. At first he denied having pain, but, on being asked if he was sure of that, admitted that he sometimes had a gnawing pain under his right shoulder when he woke from a dream.

Deep pressure over the right hypogastrium elicited tenderness. I referred him for x ray and gastroanalysis instead of psychoanalysis, with provisional diagnosis of pyloric ulcer. He proved to have a duodenal ulcer and was successfully operated upon. After the operation the dream disappeared and two years later the man was in good health and the dream had not recurred. Here the form of the dream was distinctly suggested by the man's own characterization of the pain and his dislike of rats, which was marked.

CASE IV.—This case was related to me by the patient's sister, a very intelligent teacher trained in psychology. Miss X for about two weeks had applied herself constantly to some fine embroidery by day and late at night. At the end of this time she had no pain in her eyes, but was rather fatigued. She dreamed on three successive nights as follows:

1. *She watched a multicolored, wavy aurora borealis.*

2. *She was sewing on a dress made of bright, wavy, manycolored ribbons.* (Note the lesser distance of the object dreamed of and the resemblance of the ribbons to the aurora. Also the intenser color, which was described as "dazzling.")

3. *There were "wiggly, incandescent worms of all colors" crawling over her eyelids, she could both see and feel them.* (Note closer approach and still intenser color plus feeling.)

On the fourth day she complained of slight pain in the eyes, the next day the pain was intense with flashes of light. She went to an oculist whose name the sister did not remember and was treated for retinitis. The correlation between the stimulation of the rods and cones by the capillary congestion and the visual content of the dream is obvious. This dream content apparently has no fear basis on the first two nights but may well have one on the third.

It is probable that dreams of this type will far oftener come to the notice of the general practitioner or surgeon than to that of the neuropsychiatrist and the writer would be very glad to hear of such cases. This paper is not offered as a complete exposition of the subject but in the hope of calling attention to this type of case and securing the cooperation of others in working out the field. It is not probable that a large number of cases will come into the experience of any one man, even with a hospital service. In selecting such cases the single dream should be disregarded as possibly incidental and only the dream of several repetitions with unvarying content reported.

360 COMMONWEALTH AVENUE.

A Case of Optic Atrophy in Multiple Sclerosis*

Review of Theories on Etiology and Its Influence on Treatment

By A. S. MACLAIRE, M.D.,
New York,
Associate in Neurology and Adjunct Attending Neurologist, N. Y. Post Graduate Medical School and Hospital.

Multiple sclerosis has been considered to be a disease of rare occurrence. Starr (1) quotes Jelliffe's figures of 109 cases out of 31,502 clinic patients. Mettler (2) quoting Spiller, states that it is one of the rarest diseases which we meet. Among the insane it is seen still less frequent than among the general population. Out of 19,500 admissions, Lowrey (3) only found five cases.

Primary optic atrophy in multiple sclerosis is a rare sign in this seemingly rare disease. Oppenheim (4) states that it is exceedingly rare. Foster Kennedy (5) in 1914 reported a case of multiple sclerosis in which double optic atrophy following a retrobulbar neuritis was present. He does not believe, however, that bilateral blindness can be attributed to multiple sclerosis. Crossby (6) reported a case in which both temporal halves of the disc were very pale while the nasal halves were paler than normal. He adds the further statement that atrophy of the optic nerve is seldom ever complete. Klingmann (7) records the fact that Uhthoff and others have demonstrated that the optic nerves are affected more frequently in multiple sclerosis than in tabes dorsalis; in fact, more often than in any other disease of the nervous system except cerebral tumor. He mentions one case of double optic atrophy where vision still persisted to the extent of 20/100 in the left eye and 20/200 in the right one. According to this author three per cent. of multiple sclerosis cases show a marked atrophy. He fails, however, to state whether it is complete or not. Parker (8) made the observation that papillary and retrobulbar neuritis are not unusual but that choked disc was a rare finding.

Because of a number of unusual features that this case possesses, I thought it justifiable to place it on record.

Case.—The patient, Mrs. M. W., of Bayonne, N. J., aged twenty years, American, history number 13772, came to the New York Post Graduate Medical School and Hospital in October, 1920. Her chief complaint was inability to see out of the right eye. It was not until April 15, 1921, that I first saw the case when the following history was elicited.

The onset of her illness dates back to the middle of November, 1919, when pushing a baby carriage on the street she noticed that she suddenly began to pull the carriage to the right side and become very dizzy. Her mother and sister attempted to support her but she dragged them also to the right. She then leaned against a post, felt dizzy, weak and imagined that the post was falling toward the right. In addition she felt as if something was pushing her to the right. There was no nausea, nor did she vomit. The dizziness was severe and increased upon raising her head. Her body was covered with cold perspiration. In twenty to thirty minutes she was able to start for home but with a tendency to stagger toward the right more than to the left. No eye symptoms were noticed at that time. During the remainder of the evening she sat quietly but was dizzy. The following morning she awoke apparently normal. While combing her hair she suddenly was attacked by severe vertigo, and fell across the foot of the bed. "The right eye began to jump up and down." She soon sat up but had vertigo. Everything about her, the furniture, walls, ceiling and floor seemed to rise and whirl about in circles. On attempting to walk she soon found that right sided support was necessary. A local physician called at the time diagnosed the case as one of "inward hemorrhage." The sight of the right eye was lost completely that morning. The next day the attending physician said she had had a stroke. She was able, however, to use both upper and lower extremities; no paralysis was present. The knee jerks tested at that time were normal. For the next two weeks she remained in bed and received medicine. A severe frontal headache then developed. Another physician called in to see her at the end of two weeks diagnosed the case as a "stroke and found a blood clot in the back of the eye." (Fundus examination.) The blood pressure was said to have been high. Two more weeks were spent in bed (one month in all) before she was able to get about on her feet. The dizziness had greatly disappeared but the frontal headaches still persisted.

At the Manhattan Ear, Eye, Nose, and Throat Hospital she was told that the right eye had been seriously involved. At that time nothing was distinguishable with the afflicted eye but at present she is able at times to detect light.

For the past few weeks she has been very dizzy in the mornings immediately after rising. This condition persists for three hours before she is relieved.

She had had measles and mumps at eight; pertussis at seventeen and twenty years. At thirteen (1914) a bed fell on her. She was unconscious for two days and did not recognize anyone. She complained of severe headache. Recovery was complete in one week. At sixteen (1917) she had an appendectomy. At nineteen (January, 1920) had left oophorectomy for ovarian cyst. Since her operation she has vomited often but irregularly and it was not associated with dizziness. Menstruation started at eleven, was irregular, flowing every week for three to four days, having only a period of freedom for two to three days. She became anemic as a result of this metrorrhagia. Her periods gradually lengthened until she menstruated every two to three weeks. Dysmenorrhea was absent until the age of fourteen years and has been present since. Regularity was established after the oophorectomy and is of the twenty-six to twenty-eight day type. The flow is profuse and lasts seven days.

She was married at nineteen. Dyspareunia was present for the first three months and she was frigid. After ovariectomy, above complaints were dissipated and both libido and potency became normal. There was one miscarriage at two months. No children.

---

*From the Neurological Service of Dr. F. Tilney, New York Post Graduate Medical School and Hospital

She drank coffee and tea, alcoholic liquors were not taken at all. Appetite was good. Sleep was restless. Thirst was excessive. Bowels were constipated. She had frequency, urgency and nocturia twice a night.

NEUROLOGICAL EXAMINATION (APRIL 15, 1921).

Voluntary motor system.—There were no abnormal attitudes or deformities. On toes, heels backwards, sidewise, running, the gait was normal. On attempting to walk a straight line she fell to the right. Fournier's tests were normal. Associated movements of trunk, arms and head. Right arm held quiet during walking.

Coordination.—Equilibratory, standing with feet together, eyes open—fell invariably to right. Romberg fell to right as above. Standing on one foot left and right—was unable to stand on right or left foot without falling. Right ankle and left knee gave way. Nonequilibratory—finger to nose and eyes open—normal; eyes closed—past pointed slightly with both left and right hands. Finger to finger, eyes closed—past pointed slightly. Toe to object above recumbent patient eyes open and closed, left and right normal. Heel to knee and along shin, eyes open and closed left and right normal. Adiadochokinesis was absent; dysmetria absent; skilled movements normal; handwriting perfect; conversation normal; speech test phrase (third riding artillery brigade) normal. There were abnormal, involuntary movements—irregular, rapid, coarse tremor of right hand and arm. At times it disappeared completely. Exaggerated when excited. Chiefly present at rest.

Reflexes—

Deep	Left.	Right.
Biceps	2	2
Triceps	2	2
Suprapatella	0	0
Patella	2	2+
Achilles	2	2+
Ankle Clonus	0	0
Superficial—		
Supraumbilical	2	2
Suprapubic	2	2
Upper lateral abdominal	2	2
Lower " "	1	2
Babinski	0q	0
Chaddock	0	0
Oppenheim	0	0
Gordon	0	0
Schaffer	0	0

Muscle strength was normal. There were no atrophies nor hypertrophies. Abnormal associated movements were present. The pronator sign of Strumfell was absent. Hoffmann's sign was doubtful on the right, absent on the left.

General sensory.—Touch acuity, touch localization, vibratory localization, muscle tendon localization, stereognosis localization, and barognosis localization were all normal.

Cranial nerves.—Optic nerve—January 4, 1921—Dr. Stevens reported the following—temporal border of left disc showed indications of atrophic changes in a narrow ridge. No note on right disc. Optic atrophy of entire right disc was seen. Oculomotor, trochlear and abducens—pupils equal, round, central regular, react to light and accommodation, consensual and left convergence abnormal. Right eye fails to converge. No nystagmus. Trigeminal was normal. Facial—left upper third facial paralysis. Auditory—tests were carried out by Dr. Clarence Smith. Vestibular apparatus—caloric irrigations in both ears with head in various positions showed a past pointing of three to six inches toward the right with both left and right hands, regardless of the ear irrigated. There was no nystagmus. Cochlear division—the Rinne test was positive. The glossopharyngeal, vagus, spinal accessory and hypoglossal nerves were normal.

General physical examination.—Glandular status —anterior cervical nodes palpable, posterior cervicals on right palpable, inguinals palpable; exillaries and epitrochlears not felt. In the nose there was a beginning atrophic rhinitis. The throat showed diseased tonsils. The heart and lungs were normal. The abdomen showed two operative scars, otherwise it was negative. There was frequency, urgency and nocturia. The pulse was 108 regular, small, blood pressure 130 m.m. systolic, 80 m.m. diastolic, pulse pressure 50.

Serology and laboratory tests.—The first blood Wassermann was reported doubtful, the second and third negative. The spinal fluid including the Wassermann was negative.

A urinalysis of day specimen showed a faint trace of albumin, few pus and epithelial cells: of night specimen—faint trace of albumen, few epithelial cells.

X ray examination of accessory nasal sinuses, November 24, 1920, showed slight diminution in illumination of the left maxillary antrum. The appearance was such as might be produced by hypervascularization or slight infiltration of the membranes. There was no evidence of exudate. The right sphenoid was also slightly veiled (report by Dr. William H. Meyer).

In order to further study the case more thoroughly the patient was admitted to our service on May 20, 1921. The positive findings on May 21, 1921, were as follows: Abnormal attitudes and deformities—on walking the head was kept toward the right. On walking a straight line the patient fell to the right. Fourniers's test was done very well except on returning fell to right. Associated movements of right upper extremity were lost. With both feet together, standing up straight, eyes open, she swayed to the right. Romberg fell to the right. Standing on one foot, left and right—right foot unable to bear weight; the left was normal. Nonequilibratory.

Finger to nose, the right hand was slightly ataxic; left hand uncertain. Finger to finger overreaching. Each finger to thumb was normal. Past pointed to right with right hand. Toe to object above recumbent patient—fair. Heel and knee was normal. There was a little adiadochokinesis in the right hand as well as dysmetria.

There was a rapid, rhythmical, fine tremor of right arm and hand present at rest which tended to disappear on skilled acts.

Reflexes— Deep.	*Left.*	*Right.*
Pectoral	1	1
Biceps	2	2
Triceps	2	2

Patella	2	3
Achilles	2-4	3-4
Superficial—		
Supraumbilical	2	2
Suprapubic	2	2
Upper lateral abdominal	3	3
Lower “ “	2	2
Babinski	0	0
Chaddock	0	0
Oppenheim	0	0
Schaffer	0	0
Gordon	0	0

There was a definite weakness of the right upper and lower extremities. The general sensations were normal. There was right optic atrophy, left temporal disc showed faint pallor at the extreme border. The right eye failed to converge. The position of the eyes was normal. There was no nystagmus.

Acoustic nerve tested by Dr. Clarence H. Smith. His report was as follows: "Functional examination of the auditory apparatus made May 24 and 26, 1921, showed the following results. The cochlea on each side was unimpaired, hearing being intact. The horizontal semicircular canals though impaired slightly, were still functioning. Therefore, the labyrinths and medulla were uninvolved and we were dealing with a central lesion or central lesions. Stimulation of the vertical semicircular canals by a prolonged caloric test on each side gave regular results of absence of nystagmus, vertigo or past pointing. This would point to a lesion in the upper half of the pons. There was persistent past pointing of the right arm to the right spontaneously. A test which should bring the right arm to past point to the left did not do so. This symptom pointed to a lesion involving the inward pointing centre of the right arm in the cerebellar cortex. She had also other symptoms pointing to a cerebellar lesion, adiadochokinesis, showing the right wrist to be impaired as compared to the left, inaccuracy in the finger to nose test and falling to the right in the Romberg test. I know of no single lesion which would give such a diversified picture, a lesion in the pons and one in the cerebellum, so one must think of a disseminated condition such as one would find in multiple sclerosis."

There was paresis of the upper left face. The temperature ranged from 97.8° to 99.4°, the pulse from 80 to 112, the respirations from 20 to 28.

Serology and laboratory tests.—The blood chemistry on May 23, 1921, showed urea nitrogen 13.9 mgms. per 100 c. c. of blood, sugar 0.094 mgms., and chlorides as sodium chloride 0.494 mgms. The blood count done on May 21, 1921, was reported as 8,000 white blood corpuscles, of which 68 per cent. were polymorphonuclears and 32 per cent. lymphocytes, 6 per cent. large and 26 per cent. small; hemoglobin 80 per cent. Blood Wassermann was negative. The blood culture on May 31, 1921, for spirochetes and other organisms was negative. The spinal fluid on May 31, 1921, was not under pressure and clear. The dark field examination and culture for spirochetes yielded negative findings. The spinal fluid Wassermann, the colloidal gold, Levinson test, globulin and cell count were all negative. The spinal fluid injected intraperitoneally into a rabbit failed to produce any paralysis in three weeks. Urinalysis gave faint traces of albumen and epithelial cells.

DISCUSSION AND DIAGNOSIS.

The case presented many unusual and interesting features from several angles. The ancient and famous triad of Charcot, namely, scanning speech, nystagmus and the socalled intention tremor, was absent. Neurologists of today do not wait for the development of these symptoms to diagnose multiple sclerosis. The speech in our patient was beginning to be slow though not scanning. Vesical symptoms in the form of incontinence or retention were lacking. The presence in this case of abdominal reflexes almost militated against the diagnosis of multiple sclerosis. Optic atrophy in both nasal and temporal halves of the right disc is most unusual. The strokes which the patient was supposed to have had may be interpreted as transient apoplectiform seizures. These attacks are uncommon and because of the rapid recovery from them may at first mislead the examiner to make a diagnosis of hysteria. The variability of the neurological signs at different examinations, though often present, together with cerebellar findings of past pointing, some ataxia, adiadochokinesis and Romberg all go to make up a bizarre picture.

To localize to one focus a condition so protean in its symptomatology and pathology, we were unable to do. Thus, in spite of the presence of rare and the absence of common signs, a diagnosis of multiple sclerosis was made.

ETIOLOGY.

Multiple sclerosis up to recently had been considered a disease of the nervous system with various hypothetical theories for its etiology. The new impetus given to the experimental side of the disease compels me to say a few words of the encouraging work done so far.

The older etiologies now growing obsolete, in view of the present discoveries, were given as various infections, metallic poisons, trauma, exposure, violent emotions and Strumpell's advocacy of a congenital tendency to proliferation of the glial tissue. These are the causes given to most of the neurological conditions where the true cause is as yet unknown.

In reviewing the literature on this subject we find that Bullock (9) made the first great advance. From a typical case of multiple sclerosis he drew off the spinal fluid and injected it into the rabbits and cats. Four or five of the animals developed paralysis. Simon (10) also produced the same results in rabbits. This author ran control experiments with spinal fluids of normal individuals and with positive Wassermann fluid. These controls all gave negative results.

Kuhn and Steiner (11) staining films of blood drawn from the still living paralytic animals and from the heart of the dead guineapigs and rabbits with Giemsa's stain and Loeffler's stain for cilia of bacteria reported seeing spirochetes by dark field examination. These spirochetes were different from those of Spirochæta pallida and resembled mostly the spirochete of Weil's disease yet differing from the latter in being relatively straighter and more regular.

By dark field they are very actively motile and provided at one end with a more refracting knob. In successful preparations one end appears to continue in a celium. Further observations on four cases were made, three were quite fresh, while in the fourth the disease had lasted for two years, but showed signs of recent exacerbation. With the blood and serum of these cases rabbits and guineapigs were inoculated. These animals developed a fatal disease which could be transferred to other animals by injection. By Levaditi's silver method, after preliminary fixation of the blocks in alcohol and impregnation with three per cent. silver nitrate, spirochetes were found always lying in the interior of the bloodvessels and capillaries of the liver of two guineapigs and three rabbits. Spirochetes were never found in the tissues of the animals nor were they ever found in the human organs by these authors. They (12) later confirmed their own experiments by further new successful animal inoculations in which the spirochete was found. They do not as yet definitely attribute the etiology of human multiple sclerosis to that spirochete, as it does not at present fulfill all the qualifications of Koch.

In one of their experiments a monkey was inoculated intraperitoneally in March, 1917. Temporary signs of paralysis in the legs were first noticed in February, 1918. In June, 1918, the paralysis returned permanently and in July, 1918, when he was killed, the brain showed macroscopically circumscript gray spots in the white matter. The microscopic pictures were identical with those found in human multiple sclerosis. Spirochetes were not recovered from the monkey.

Siemerling (13) made the most important advance of all. He found by dark field examination living spirochetes in two sections from the brain of a man who died of multiple sclerosis. Thus was the work of Kuhn and Steiner confirmed. Schuster (14) also demonstrated fine spirochetes below the cortex in sections of the brain of a case of multiple sclerosis. Marinesco (15) injected six guineapigs by the intracerebral method with three c. c. of serum from two cases. By dark field examination of the cerebrospinal fluid taken from the fourth ventricle he was able to demonstrate large numbers of living and motile spirochetes. These animals showed paralysis before death. Hoffman (16) suggests that multiple sclerosis like neurosyphilis may be the secondary result of a previous spirochetal infection of varying duration.

In our case, we were unable to produce any paralysis in the injected rabbit. The spinal fluid was injected intraperitoneally into a rabbit. No changes were noted in three weeks and the experiment was considered a failure. The failure in one experiment especially from an atypical case should not be used to condemn the findings of reliable workers. The only thing we can state at present is that we were unable to confirm the work of others. We hope, however, to continue our studies and shall make further reports on a larger series.

RECENT SEROLOGICAL STUDIES.

It is a well known scientific fact that a general paretic colloidal gold curve has been obtained in general paresis, plumbism, tuberculous meningitis, brain tumor and multiple sclerosis. It is, however, only in general paresis and multiple sclerosis that the colloidal gold reaction has been present in any degree of regularity. In the other three conditions it is merely incidental.

Moore (17), working on twenty-eight cases diagnosed as multiple sclerosis, twenty of which were definite and eight doubtful, found a pleocytosis in sixteen cases. He considered anything over five cells as abnormal. Globulin was present in twenty-five cases, excessive in ten. The spinal fluid and blood Wassermanns were negative in all cases. In eighteen cases the colloidal gold curve was of the paretic type, luetic in three and negative in seven. Thus, out of twenty certain cases of multiple sclerosis, a general paretic gold curve together with a positive globulin reaction appeared in eighteen cases, or ninety per cent.

The percentage is sufficiently high to warrant its use in diagnosis. Thus excluding the rare cases of plumbism, tuberculous meningitis and brain tumor that give the reaction also, a general paretic curve is indicative of either neurosyphilis or multiple sclerosis. The negative blood and spinal fluid Wassermann serves to differentiate between the remaining two conditions, except in long treated cases of lues where the Wassermann has become negative before the colloidal gold curve.

Adams (18) reporting preliminary results to the Medical Research Council on experimental investigation into the etiology of multiple sclerosis, states the following. All but two out of the forty-one cases examined gave either a paretic or luetic gold curve. Five showed a paretic curve, the remainder a luetic. The average number of cells was five small lymphocytes. Centrifuged specimens showed in two doubtful cases actively metile spirochetes. Attempts made to stain them failed. The protein content was present in seven cases. The Wassermann reaction was positive in nine cases, four both in spinal fluid and blood, two positive in the spinal fluid and negative in the blood, two positive in the blood and negative in the spinal fluid, one positive in spinal fluid but the blood was not examined. This simply means that lues may be coexistent rather than the cause of multiple sclerosis. Though the type of lesion is different in the two diseases, yet the selective site of the virus is the same.

TREATMENT.

Adams (18) reports the results of twenty-two cases treated with intravenous novarsenobilin, biniodide of mercury by mouth and intramine intramuscularly. Thirteen out of the twenty-two cases improved noticeably and nine have not been benefited.

Perdran and Stebbing (19) treated bedridden cases with salvarsan intravenously and metallic mercury intramuscularly. The sphincteric control was regained and the paraplegia disappeared, leaving a slight paresis of the legs. Relief was had for two years, when recurrence with symptoms simulating general paresis were had. The patient died and autopsy revealed typical soft pink patches of sclerosis in the spinal cord, medulla and white matter of the brain.

German authors have preferred the use of silver salvarsan, using it intravenously alone without the additional metallic mercury. The results claimed by them are remarkable.

SUMMARY.

Should the spirochete eventually prove to be the cause of the disease, we may then hope for the same results in multiple sclerosis that we are today enjoying in syphilis. Like lues early cases will give us the best results.

Salvarsan having a selective action on spirochetes will, in all probability, be the accepted drug. The form of salvarsan, whether it be the silver or the neo preparation, is yet to be determined.

We at the Post Graduate Hospital shall continue our study of the subject and hope to report more fully on a large number of cases in the future.

I wish to take the opportunity to thank Dr. Tilney and Dr. Osnato for permission to report this unusual case.

Atypical Amyotrophic Lateral Sclerosis

By E. D. FRIEDMAN, M. D.,
New York,
Assistant Attending Physician to the Neurological Service, Bellevue Hospital, Adjunct Neurologist Mount Sinai Hospital.

The classical type of this disease is familiar to most practitioners of medicine. There usually are pyramidal tract signs in combination with fibrillation and atrophic wasting of the muscles of the shoulder girdle and of the intrinsic muscles of the hand. Bulbar phenomena constitute an essential and usually terminal feature of the disease.

I have recently had under our observation, cases belonging in this group but deviating in their clinical course from the type commonly described. To my mind, they illustrate the fundamental pathology of the disease, with a mode of onset which, while similar in nature, yet differs in anatomical localization.

Case I.—Charles T., aged fifty-one, painter until one year ago, married, born in Germany, admitted to the service of Dr. Foster Kennedy, at Bellevue Hospital on February 18, 1921.

His chief complaint was weakness of the arms, and inability to walk. One daughter was mentally retarded and subject to fits of unconsciousness with paralysis of one side and impaired memory.

The patient had socalled rheumatism ten years ago; relieved by baking. He suffered from a temporary wrist drop ten years ago. Eight years ago he was treated for painter's colic at the Roosevelt Hospital. The limbs were not involved at that time. He also complained of impaired vision. He had influenza in 1920. Later the patient experienced an attack of colicky pain with profuse perspiration which was diagnosed as lead colic. He admitted a Neisserian infection, he took alcohol moderately and smoked little. He had had recurring attacks of bronchitis (socalled weak chest).

The present illness began a year ago with cramps and pain, in the left leg below the knee, increasing in severity and rapidly involving also the right leg. He gave up work eight months ago. Twelve months ago he experienced numbness in the hands but no weakness. While a lumbar puncture was being done, he felt a pain radiating down to his toes and a feeling of icy coldness which he could not get rid of for several days. He maintains that the left great toe seemed to get weak from the time of the puncture onward. He had not been able to extend it since. Both feet felt cold and have become wasted. The calves and thighs also had become atrophic. Ever since the onset, he was troubled by involuntary jerkings of the legs and arms and a feeling as if they were asleep. He had found increasing difficulty in walking, particularly in lifting his legs to go upstairs; he often fell and found it impossible to get up. He says he fell because he tripped over his toes. There were no bladder symptoms; blue line was never demonstrable.

The patient was mentally alert and cooperated well in the examination. Smell was normal. Right eye was damaged by an accident at the age of seventeen and since then he could read only with the aid of glasses. He believed that his eye sight had been impaired since the attack of lead colic. The pupils were normal. Ocular muscles showed no abnormalities. Motor and sensory fifth were normal. Patient had an old deafness of the right ear with impairment of air conduction. Uvula deviated to the left, on voluntary innervation. Patient had great difficulty in coughing but no choking spells. His tongue protruded straight, was not atrophic and showed no fibrillation. There was marked weakness of the quadriceps and anterior tibial groups. He showed double foot drop, bilaterally impaired dorsiflexion of the ankles with wasting of the extremities, especially below the knee (more marked on the right) fibrillation and involuntary jerkings. Previously he could lift a weight of fifty pounds by his feet; on examination he could perform no movements against resistance. All the toes could be flexed except the great toes. The foot could be everted but there was no extension of the toes or the ankle joints. The muscles of the calf and thigh were flabby. There was difficulty in flexing leg on the thigh. Gait was shuffling. His feet were raised with much effort to avoid trailing his toes on the ground. The patient had difficulty in balancing when standing still but there was no true Romberg phenomenon. The upper extremities showed fibrillation in the hands and shoulder girdle but no atrophy or weakness. On the sensory side, the patient experiences acute attacks of gnawing pain in the calves and lumbar region, with spasmodic tightening of all the muscles of the foot and leg. No marked objective sensory changes were found in the limbs, although there was dulling of all forms of sensation; over the feet possibly due to acrocyanosis. Sensation over the body was normal except for an indefinite level behind and front, extending to the clavicle, above which pinprick was more definitely felt. Patient complained of paresthesias in the hands. No spinal tenderness. Abdominals were not obtained. Knee jerks were present and equal, ankle jerks active with ankle clonus on the left. Plantars could not be studied on account of toe drop. Fibrillation was also found in the calf and thigh muscles. There was also a distinct reaction of degeneration in the extensors of the lower leg, calf muscles and flexors of the knee. Partial reaction of degeneration in the extensors of the toes was more marked on the left. A similar change was found in the quadriceps group more definite on the right. No bladder symptoms. After some time in the hospital edema of the legs developed. Blood chemistry was normal. Patient showed a marked emphysema and moderate atherosclerosis. Blood pressure was 154/90. Electrocardiogram indicated a poor myocardium, slight left ventricular preponderance, no block.

The patient was then transferred to the Montefiore Hospital (September 27, 1921). He could not stand or walk unsupported. The deep reflexes were active, abdominals and cremasterics were absent, double foot drop persisted and there was almost complete loss of power in the lower extremities, with marked atrophy of all the muscles, especially those of the thigh. Rossolimo and Mendel-Bechterew signs were positive on the left. Paralysis of the extensor longus hallucis eliminated the Babinski. Later on there developed some weakness of the left face with widening of the left palpebral fissure. There was a coarse tremor of the face, lips and tongue with slight fibrillation of the tongue. Patient began to experience difficulty in swallowing solids. There was weakness of both sternomastoids and atrophy of the deltoid and biceps with fibrillation both in the muscles of the shoulder girdle and in the intrinsic muscles of the hand. He gradually lost power in the left hand. At times difficulty in breathing developed. He died April 9, 1922 with typical bulbar manifestations. Mentality was clear to the end. Urine was negative except for a faint trace of albumin; no lead was found. Blood count: Red blood cells, 3,400,000; hemoglobin, 65 per cent.; White blood cells, 3,400; polynuclears 66 per cent.; lymphocytes 30 per cent.; eosinophiles 2; basophiles 1; monocytes 11. Blood Wassermann was negative. Blood pressure 170/120. Cerebrospinal fluid showed no abnormalities.

On autopsy the brain alone was examined, weight 1300 gr. There was edema with slight opacity of the pia over the parietal and frontal regions; vessels at the base, normal. The medulla was smaller than normal. On section there was injection of capillaries throughout and a globular enlargement of the choroid plexus on both sides at about the junction of the lateral and inferior surface. The entire plexus was extremely congested. The cord was not obtained.

Case II.—No. 208,429. Regina H., aged fifty-five, born in Hungary, married, housewife. Admitted March 5, 1921 to the service of Dr. B. Sachs at Mt. Sinai Hospital, discharged May 31, 1921.

The chief complaint was paralysis of the right leg for six months. The family history was negative. The patient had never been pregnant. Menses began at fifteen and were regular. Menopause came on five years ago. Patient was always in good health except that she had had a chronic nonproductive winter cough for years. She experienced occasional dyspnea, tachycardia and palpitation on exertion.

The onset of her present illness was gradual six months ago, when the patient noticed that the right ankle turned easily. She would fall at times. The right leg became progressively weaker until she was unable to stand. She was in bed or chair for two months. Lately she had noticed weakness in the other foot, leg and lumbar muscles. The patient could not sit up unaided, had no pain, paresthesias or sensory changes. The right leg had gotten thinner and weaker so that she was able to move only the toes. There was some tenderness along the posterior aspect of the thigh. Patient thought her arms were also thinner. There were no bladder or rectal symptoms. She experienced vague pains in the abdomen on attempting to sit up. "Blood test" some time ago was negative. She was treated for visceroptosis. Her condition has gotten slowly but progressively worse.

She was mentally clear. The right pupil was larger than the left, both a bit irregular and sluggish to light; slight ptosis of the left upper lid was present. Other cranial nerves showed no gross abnormalities. The heart was enlarged to the left; there was some accentuation of the aortic second sound. Patient's breathing is chiefly abdominal. There was paralysis of both lower extremities especially the right, except for movement of the toes and slight dorsiflexion of the feet. There was also some paresis of both upper extremities and the muscles of the lower back seemed weak. Wasting and hypotonia of the muscles of the back was noted. Abdominal reflexes were absent. The right knee jerk was absent, the left, feeble; right ankle jerk was absent and the left, feeble. There was a questionable left Babinski; no sensory changes were observed. There was distinct wasting of the quadriceps, anterior tibial and posterior tibial groups and of the gluteals.

Fibrillation was present. The spinal fluid was clear, under normal pressure and showed no cells. Fundi showed slight pigmentary changes, more marked in the right eye but they were otherwise negative. On account of the irregular and sluggish pupils, the patient was treated antiluetically for a time without apparent benefit. The patient had vague sensory changes from D 11 to L 3 on the right and some local tenderness over the lower dorsal spine. With the galvanic current there was slow contraction in the tibialis anticus, quadriceps and hamstring groups. KCC however, was greater than ACC. There was diminished faradic response in the peroneal and gastrocnemius group. Soon afterward, there was noted wasting of the intrinsic muscles of the hand with increasing weakness of the arm, especially on the right. Fibrillary twitchings were noted here and in the tongue. The tongue deviated to the right when protruded. The patient had a number of coughing spells during which she rapidly became cyanosed. Wrinkling of the right half of the tongue was noted. Later there was found weakness of the right upper extremity, chiefly of the extensors, and the right triceps jerk was feeble. Blood examination gave the following results: Hemoglobin 65 per cent., red blood cells, 3,500,000, white blood cells, 9,000, polynuclears 70 per cent., lymphocytes 20 per cent., monocytes 6, eosinophiles 2, basophiles 2. On May 28th, patient suddenly became cyanotic and dyspneic. (Pulse 120, respiration 40.) Patient showed a weak cough, the larynx was not examined. She had a number of attacks of difficulty in breathing with choking spells all through the month of April. On the 31st of April, she had a particularly severe attack, became very much alarmed and left the hospital against advice. The urine was negative. The blood Wassermann was negative, spinal fluid Wassermann proved negative. Fehling's solution was not reduced by the spinal fluid. X ray of the dorsal and lumbar spine was negative. X ray of the pelvis was negative. There was some arthritis of the right knee. The patient died soon afterwards at her own home.

Case III.—226,502. M. B., born in France, aged sixty-one, widow, housewife. The patient was admitted January 15, 1923 and discharged February 12, 1923. Her chief complaint was an inability to walk and difficulty in speech for ten months. The family history was negative.

She had had meningitis and typhoid fever thirty years ago, suffered from rheumatic fever ten years ago and had influenza three years ago. Patient has been subject to right sided headache for several years. She had had two children, no miscarriages. Menopause came on seven years ago. The present illness began ten months ago with weakness of the right leg and difficulty in speech. The weakness of the right leg became rapidly worse, soon the left leg became involved. For the past few months, she is able to walk only with the support of a cane. Four months ago she experienced dull pain in back of the neck and shoulders; there was no radiation to the arm; no paresis of hands or arms; difficulty in speaking has been more marked lately. There was occasional disturbance in swallowing and in passing food backward from the mouth to the pharynx. Patient had had a disagreeable sensation in the tongue.

The physical examination showed that the pupils were slightly irregular. Teeth seemed in poor condition. Tongue was protruded in the median line and tremulous: On active innervation the uvula deviated to the right. Marked weakness of the right lower extremity was present; there was kyphosis of the dorsal spine; speech was slow, thick and had a nasal twang; it was distinctly dysarthric. Patient noted jerkings in the right foot: Slight right facial weakness was present, visual fields and fundi were normal. Patient could not spit out well, nor pucker her lips. Had difficulty in passing food backwards, tongue deviated to the left; it showed fibrillation with some atrophy and furrowing. The right knee jerk and ankle jerk were diminished, those of the left were more active, bilateral Babinski and Oppenheim were present (right greater than left). Abdominals were diminished on the right. There was distinct weakness of the right lower extremity with hypotonia. There were similar changes in the left leg but less marked. Upper extremities were normal and sensation was intact. Blood pressure was 170/120. Examination of the larynx was negative. Blood examination showed the following: Hemoglobin 100 per cent., red blood cells, 5,120,000, white blood cells, 8,600 with a normal differential count. Patient said "tongue is as lazy to talk as the legs are to walk." Of late she had experienced difficulty in mastication. The bolus could not be passed to the pharynx, patient could not whistle. The tongue deviated to the left. Twitchings occurred in the left face. There was foot drop on the right and the peroneal group on the left also seemed weak. Temperature, respiration and pulse normal. Blood Wassermann proved negative. Examination of the cerebrospinal fluid showed no cells, no increase in globulin. Wassermann was negative. X ray of the sinuses was negative. All three of these cases showed in common, a primary involvement of the lower extremities. The findings included muscular wasting with diminution to abolition of the deep reflexes, and changes in the electrical reactions. In Case I. there were in addition, similar findings in the upper extremities and shoulder girdle. The bulbar signs appeared only terminally. In Cases II. and III., the bulbar phenomena while not definite at first formed part of the clinical picture for some time. In all of the cases there were mild evidences of pyramidal tract lesion. In Case I. the toe drop precluded the possibility of eliciting the Babinski sign. However, the absence of abdominal wall reflexes and the left ankle clonus were significant in this regard. In Case II, the absence of the abdominals in the nulliparous woman and the suspicious left Babinski, also served as evidence of pyramidal tract involvement. In Case III. the pyramidal tract signs were definite.

All of these cases illustrate what Schaffer has termed system trophism. He looks upon the upper and lower motor neurons as parts of a motor system and it might be worth while to consider this disease as one involving this system. This will explain an apparently paradoxical phenomenon in this disease, namely exaggerated deep reflexes even in limbs with extensive degenerative atrophy. This of course depends upon the predominance of the pyramidal tract injury over that of the anterior horn lesion.

Many of these cases have been labelled chronic anterior poliomyelitis. One cannot negate the occasional incidence of a pure chronic anterior poliomyelitis such as occurs, for example, in cases described by Dana and others on a luetic basis. Yet I, in common with most other observers, would include this combination of bulbar phenomena, anterior horn lesion and pyramidal tract signs under the generic syndrome, amyotrophic lateral sclerosis. In some of the cases, the bulbar signs dominate the clinical picture. In others, perhaps, the anterior horn lesion stands out as the conspicuous feature of the disease, while in a third group the lateral sclerosis with resulting pyramidal tract phenomena preponderate.

With this classification in mind, I have collected this group of cases, illustrating atypical forms of this disease which are frequently misunderstood and incorrectly labelled. I wish to express my sincere thanks to Dr. B. Sachs and Dr. Foster Kennedy for permission to report the cases from their respective services.

Arteriosclerosis of the Nervous System: Remarks on Etiology and Symptomatology*

By GEORGE E. PRICE, M.D.,
Spokane, Wash.

BASIS OF STUDY.

We have so much to learn about arteriosclerosis of the nervous system that it justifies a careful analysis of any considerable number of cases. A writer not long ago said that cerebrospinal arteriosclerosis was but little understood, and MacCullum (1), writing of arteriosclerosis in general, feels that we are extraordinarily ignorant with respect to this common affection. That ideas relative to the subject have been changing, is shown by the fact that in the last edition of *Osler and McCrae,* the chapter on arteriosclerosis was rewritten.

My interest in the subject is chiefly clinical; the material forming the basis of study for this paper consisting of the records of one hundred cases from the Philadelphia General Hospital (collected when connected with that institution), and from private practice.

ETIOLOGY.

In a perusal of numerous articles on arteriosclerosis, one cannot help but be impressed by the rather formidable list of etiologic factors enumerated. Among these we find age, sex, heredity, hypertension, infection or toxemia, diet, muscular exertion, lack of exercise, nervous strain, obesity, and glandular dysfunction.

Age.—No article on arteriosclerosis would be allowed to pass the censor without a reference to the moss grown and time worn but nevertheless true quotation: "A man is as old as his arteries." While change in the arteries is a necessary accompaniment of involution, of senility, age is relative, and can not always, pathologically, be estimated by the number of years the individual has lived. In my series, the average age of the patients when examined was 64.5 years, and it is interesting in this connection to note the close approximation to Woltman's (2) average in 146 cases studied, namely, sixty-three years. That we should find a wide variation in the ages of our arteriosclerotic patients is not surprising. They ranged all the way from forty-nine to eighty-five years, two being fifty, and two fifty-two years of age. What to me seems of more importance than the age of the patient when examined, is the age at which the symptoms were first noticed. This was recorded in seventy-four cases, and averaged 60.9 years.

Sex.—Seventy-nine of the cases were males, and twenty-one females. These figures are misleading, as a large proportion were collected from the Blockley records, where males greatly predominated. Of the private patients, a true index, the ratio was two males to one female, again coinciding with Woltman's statistics, in which males predominated (sixty-four per cent.). Dercum (3), in discussing a paper before the College of Physicians of Philadelphia, made the statement that mental and nervous effects due to arteriosclerosis greatly predominated in the male; arteriosclerotic dementia, for instance, being quite rare in the female, while intermittent claudication is practically a male disease. Norris in closing the discussion said that one sees many less cases of aortic aneurysm in women than in men, and one rarely sees extreme degrees of pipestem arteries in women.

Heredity.—All other factors being equal, there is undeniably a distinct tendency in certain families toward early arterial degeneration. Some years ago, I met a physician, who, then in the late thirties, presented a marked arcus senilis. This was so striking that I untactfully remarked about it, and was told by the gentleman that practically all of his people died of cardiovascular troubles before they were fifty. Different species of animals vary greatly as to longevity, but no adequate explanation has been offered as to why in the human species, there should be familial variations with regard to arterial degeneration and in consequence of this, to expectancy of life. Osler commented on the influence of heredity by saying that "bad material was used in the tubing," but did not tell us why the material was faulty.

In reviewing the case histories from the viewpoint of heredity, nothing of any value was found to report, but possibly a little of interest. In twenty-nine instances where the age of the parents at the time of death was recorded, of the fifty-eight parents, two thirds of the number had lived to exceed three score years and ten. Twenty-seven died between seventy and eighty years, nine between eighty and ninety years, and one died at ninety-five years. The majority were of English and Irish descent. One arteriosclerotic woman of fifty-three years who had a stroke, lost a mother and two sisters from apoplectic attacks, and a third sister, still living, had a hemiplegia as the result of a stroke. Another patient, a man of seventy, gave the following unusual family history. His father died when the patient was a child, his mother died at eighty-one, one brother died at thirty-nine, one brother was living and in good health at eighty, one sister died at seventy-six, a second sister at seventy-eight, and a third sister died at eighty-two.

---

*Read before the Portland Academy of Medicine, February 8, 1923.

Hypertension.—It is commonly recognized that persistent high blood pressure leads to arteriosclerosis, but we also know that high blood pressure is not always indicative of arteriosclerosis, and that the presence of arteriosclerosis does not always mean that there is hypertension. "The terms are not interchangeable." (Norris.) Cardiac myofibrosis and cardiac dilatation are common in arteriosclerosis and with a weakened pump it is obvious that the force of the blood stream is diminished and in consequence, the blood pressure lowered. However, the average blood pressure of the patients in my series was high: 104 diastolic and 177 systolic. The three highest blood pressures recorded were: diastolic, 120; systolic, 280; diastolic, 155; systolic, 235; diastolic, 140; systolic 230. On the other hand, some of the pressures registered were abnormally low, the three lowest being: diastolic, 60; systolic, 100; diastolic, 80; systolic, 110; diastolic, 70; systolic, 112.

Infection.—Just what rôle is played by the various infections is difficult to estimate—and opinions vary. Of the various infectious diseases those most emphasized have been typhoid fever (Thayer), tuberculosis and syphilis. Focal infection has also many advocates as being an etiological factor in the production of arteriosclerosis. O'Hare, in discussing vascular hypertension, writes: "It is surprising how little part post infections or even latent infectious foci play in this disease."

PREVIOUS ILLNESS.

In reviewing the previous medical history of the patients from the standpoint of infections, typhoid fever was recorded twelve times, smallpox nine times, pneumonia and rheumatism each eight times; malaria, scarlet fever and influenza four times. One patient gave a history of severe puerperal infection. Several had multiple infections, such as smallpox, malaria, syphilis and gonorrhea, malaria, scarlet fever and smallpox; smallpox, typhoid and pneumonia. Two men admitted having gonorrhea five times and one man confessed to six such attacks.

RÔLE OF SYPHILIS.

I have never felt that syphilis was a potent factor in the production of cerebrospinal arteriosclerosis. Syphilis is inflammatory and destructive, while arterio capillary fibrosis is really degenerative. In the 100 cases, a positive Wassermann was recorded in only two instances and in five other patients a positive luetic history was obtained, although blood and spinal fluid Wassermann tests were negative. Not every case was examined for the Wassermann reaction, and while realizing that a routine examination of the blood and spinal fluid would possibly have raised the percentage of luetics in the series, it is safe to say that the incidence of syphilis was no higher than in a like number of non-arteriosclerotic patients, or for that matter, in the average of the community. Indeed, I feel that the argument could be made even stronger. The majority of the patients were well advanced in years, and the pathology of syphilis does not tend toward longevity. Thus, while the frequency with which syphilis produces disease of the aorta is well recognized, Bittorf found that in fifty-four cases of sclerosis of the aorta, the average age was 55.6 years, but the syphilitic cases averaged ten years younger.

INFECTIONS.

An interesting contribution on the relation of arteriosclerosis and cardiovascular disease to infectious diseases by Ophüles appeared recently (4). The records of five hundred consecutive complete necropsies were studied with reference to preceding infections (determined by the clinical histories and careful anatomic study.) The cases were divided into two groups—those in which all history or signs of previous infection were absent, and those in which such had been detected. It was found that chronic arterial disease was almost entirely lacking in the first group, but was found frequently in second group. It was further found that the connection did not hold in all infectious diseases, but was fairly well limited to chronic septic (rheumatic) conditions.

If this work is substantiated, it will constitute an important chapter on the etiology of arteriosclerosis, where so much has been speculation and opinion without definite proof.

Intoxications.—Much has been written regarding the effects of alcohol and tobacco in the production of arteriosclerosis. In the series, notwithstanding the fact that a large number of the cases were recruited from the derelicts at Blockley, in at least one third of the patients in whom a history could be obtained, no alcohol had been used. Something over one third had used alcohol to excess, while less than one third had used alcohol only moderately; nor was there anything to indicate that the arteriosclerosis was more intense or more marked in those who had used alcohol to excess than in the non users.

The number admitting excessive indulgence in tobacco was eleven, with fourteen moderate users of the weed. Twenty-three had never used tobacco and no history was given in fifty-two instances.

Certainly of late years, the importance of both alcohol and tobacco in the causation of arteriosclerosis has ceased to occupy so prominent a place as formerly. I believe that the human race has acquired more or less tolerance toward these poisons, and that we cannot use as comparisons the results of experimental researches upon animals. As Lloyd has expressed it, the combined ancestors of most any one of us have imbibed enough alcohol to float a battleship.

In four of the patients, lead may have been a factor; three were painters, one of whom had been treated twice for lead poisoning. The fourth case, one of the most marked examples of arteriosclerosis I have ever seen, was a printer who for years had set type by hand.

Diet.—There is still considerable discussion as to the rôle played by an excess of protein food in the diet. Most writers consider it as established that this is deleterious, while Mosenthal holds that there is no definite proof that a diet high in proteins, especially meats, is one of the main etiologic factors.

Ignatowski, (5); Newburgh and Squier, (6); and Newburgh and Clarkson, (7), have produced definite arteriosclerosis in rabbits by a diet rich in animal protein. The latter writers, while emphasizing the close resemblance between their experimental arteriosclerosis and the disease as it occurs in man, do not assert that the abuse of protein causes human arteriosclerosis, as "the vascular system of omnivorous man may have acquired an insusceptibility to the products of protein metabolism, not possessed by the herbivorous rabbit."

While not able to give any convincing facts or figures it has been my clinical experience that the most important thing is to restrict the total food intake. It is not so much what goes into the furnace as it is that the fuel be completely consumed. Middle age usually brings a lessening in the amount of exercise taken, but not a corresponding decrease in the appetite, therefore most people past the age of forty tend to overeat. The elder Horatio C. Wood, whose characteristic and forceful way of driving home a truth with an epigram is well remembered by his old students, once said in a clinical lecture, that "nine tenths of the American people dig their own graves with their teeth."

Muscular exertion.—There would seem to be no argument against the statement that continued hard physical work and exposure are contributing factors. Yet the same thing can be said of prolonged, hard brain work, especially if combined with mental worry and anxiety. It is obvious that a parallel can be drawn between the influence of hard work and exposure and the predominance of arteriosclerosis in the male sex. One of the female patients presenting marked general arteriosclerosis and dementia was a Russian, who in her younger days had worked in the fields with the men.

OCCUPATION.

In the series, the most conspicuous thing about the occupation of the patients, was the large and varied number represented, between forty and fifty, running all the way from ragpicker and street sweeper to bankers, merchants, and retired gentlemen of leisure. One was a dentist, one was a judge, while bricklayers and carpenters were represented. It will be remembered that this was before the day of what we might term nonlabor unions.

Laborers predominated, being eighteen in number, with farmers (nine) coming next. As would be expected, the locality from which the patients were drafted had something to do with their occupation, as most of the laborers were recruited from the Blockley wards and all of the farmers from the Northwest.

VARIOUS FACTORS TO BE CONSIDERED.

After all is said about the various special causes of arteriosclerosis, the condition really represents the sum total of the stress and strain of life, both physical and mental, to which the individual has been subjected, infections, toxemia, hard work, exposure, all contributing their part.

SYMPTOMS.

The symptoms of arteriosclerosis of the nervous system are naturally divided into those referable to the brain, to the spinal cord, and to the peripheral nerves.

CEREBRAL.

Of the cerebral symptoms, vertigo was recorded in forty-six per cent. of the cases, and was the most common single symptom. Stein (8), in a study of 1,026 cases, states that in the majority of arteriosclerotic patients, the ear conditions overshadow pathological conditions elsewhere, vertigo being usually the symptom for which the patients are sent for ear examination. Tinnitus is less common than vertigo, and a gradual impairment of hearing is not infrequent.

AUDITORY APPARATUS.

Eight cases in the series were recorded as having either total or marked deafness and eight more were found to have moderate or slight impairment of hearing. In the ordinary routine examination of patients, the auditory apparatus does not, as a rule, receive the attention it deserves, and slight or moderate deafness is likely to be overlooked, especially if unilateral. Moreover, unless the examination is made by an otologist, there is no information as to the nature of the deafness or of its cause.

AFFECTIVE CHANGES.

About one quarter of the patients presented definite amnesia for recent events, in more or less association with a gradual impairment of attention and association of ideas. Emotionalism was not infrequent, being most conspicuous in the pseudobulbar patients.

HEADACHE.

Headache or head pain was common, the most characteristic form being that present upon waking, gradually ameliorating as the patient would be up and about. Pain referred to the body and extremities was often complained of, but not nearly as frequently as head pain. Paresthesias were common, especially of the lower extremities, next of the upper limbs. Definite sensory loss was infrequent, but blunting of sensibility in the lower extremities was occasionally recorded.

EYE SYMPTOMS.

The pupils were found to be small and sluggish in twenty-five per cent. of the cases. This is the characteristic senile pupil. In two instances the pupils were described as being fixed. Arcus senilis was present in sixteen per cent. of patients. Homonomous hemianopsia, evidently from hemorrhage, was found twice.

It is an axiom that retinal arteriosclerosis always means cerebral arteriosclerosis, although the latter may be present without the former. Among the ophthalmoscopic signs of arteriosclerosis are a narrowing of the arteries and a dilatation of the veins, with irregularities in the calibre of the arteries, due to local thickenings of the intima. The veins may show constrictions where they are crossed by the rigid arteries. The arteries may be unduly tortuous and present an excessive brightness of the light streak, the socalled silver-wire appearance.

Miliary aneurysms may occur in the retinal arteries as well as in the cerebral vessels, and slight hemorrhages into the retina are occasionally seen.

A corkscrew appearance of some of the smaller arterial twigs, especially those in the immediate region of the macula, has been emphasized by Veasey (9), as one of the earliest signs or arteriosclerosis of the retinal vessels.

APOPLEXY.

Apoplectic attacks were noted in over one quarter of the cases. This is in marked divergence from Woltman's (2) finding of such occurrence in only three per cent. of his patients, leading him to state that too much importance is attached to them as requisites in making a diagnosis of cerebral arteriosclerosis. One cannot help but believe that the surgical character of the clinic from which Woltman drew his material may explain the difference in statistics.

Twenty of the apoplectic cases were of the hemiplegic type, and five patients gave a history of strokes on both sides, or double hemiplegia. Three in the series had apoplectiform attacks followed by marked mental confusion, but without any paralytic symptoms. One patient gave a history of having had five strokes and one of the hemiplegics was a beautiful example of motor aphasia resulting from a right sided cerebral lesion, the patient being left handed. In two instances the hemorrhage had involved the optic tract of one side, causing a homonomous hemianopsia. Sclerotic radials were found thirty-four times and sclerotic temporal arteries sixteen times.

GAIT.

The gait was described as ataxic in eighteen cases, spastic in two, and combined spastic and ataxic in four. The stuttering or stammering gait, which may be considered as pathognomonic of cerebral arteriosclerosis was found in eight patients. While many arteriosclerotics will fall suddenly because of an attack of vertigo, others will fall independently of vertigo or ataxia, from a sudden giving way of the legs of circulatory origin. This was recorded in sixteen patients, and probably occurred in a larger number. Epileptiform attacks occurred in twelve instances—therefore in twelve per cent. of patients. Eleven of these had convulsive seizures, and one a psychic epileptic equivalent. Of the twelve cases, only one gave any history or laboratory findings indicative of syphilis.

AGE.

The average age of the patients when the convulsions first appeared was 54.9 years. In no instance did the attacks begin before fifty and only once at sixty or over (sixty years.) A rather striking clinical fact was the long duration of the attacks, the average duration of the convulsive seizures at the time the history was obtained being 6.9 years. One man of seventy had been subject to convulsions for thirteen years, another of seventy-two for thirteen years, one of sixty-nine for twelve years, and one of sixty-four for eleven years. It will be seen, therefore, that epileptiform attacks, occurring in the aged, are not of bad prognostic significance as regards life.

CONVULSIONS.

In no instance were the convulsions of the Jacksonian type, although it is conceivable that localized convulsions could occur as the direct result of a localized arteriosclerotic lesion, such as an aneurysmal dilatation or small cortical hemorrhage.

In its essential features, the convulsion of an arteriosclerotic does not differ from that of idiopathic epilepsy.

EPISTAXIS.

Epistaxis, while not really a cerebral symptom, occurs frequently as one of the earlier manifestations of arteriosclerosis and we should, in this connection, be suspicious of spontaneous bleeding from the nose in a person past forty, when none of the usual causes are operative.

Although present to a slight extent in a larger number of patients, spinal symptoms were prominent in twenty-one cases, and were grouped as follows:—tabetic four, spastic four, ataxic paraplegia eleven, amyotrophic lateral sclerosis one, transverse one.

Of the four cases classed as tabetic, all had lost knee jerks, two had marked ataxia, and two had sphincter involvement. The socalled spastic cases all presented increased reflexes and stiffness of movement, but only one of the four gave a definite Babinski; one gave no toe response to plantar irritation, and two were recorded as having no Babinski. All of the eleven cases grouped as ataxic paraplegias, had ataxia, Romberg's sign, and increased reflexes, four of the number having double Babinski.

NEUROLOGICAL SYMPTOMS.

The amyotrophic lateral case was classic, with muscular atrophy, affecting chiefly the intrinsic muscles of the hands and the posterior muscles of the shoulder girdle. Fibrillation was present, the patella tendon reflexes increased, Babinski's sign present on the left and absent on the right. As the patient, a woman, was seventy-two years of age and the condition had developed gradually within a year and she had dementia, dyspnea, occasional vertigo, a systolic murmur at the apex, and a blood pressure of diastolic 80, systolic 170, I felt justified in attributing the cord disturbance to circulatory changes.

The patient classed as a transverse cord lesion was a woman of seventy-one years, apparently well until one year prior to the examination. She first noticed a prickling sensation of her toes. Two weeks later her knees suddenly gave way under her and she fell. Bladder incontinence developed only ten days before she was examined. Examination revealed sensory loss to a point five cm. above the umbilicus; she could move her toes and ankles, flex and extend the right leg, but was unable to move the left knee or hip. There was considerable muscular atrophy of the lower extremities. Patella tendon reflexes were increased; double Babinski present. Blood pressure diastolic 100, systolic 200. This patient did not present the blood picture of pernicious anemia.

I would emphasize the frequency of the ataxic paraplegia syndrome and call attention to its resemblance to subacute combined sclerosis of the cord as seen in pernicious anemia.

Peripheral nerve involvement was present to a considerable degree in only four patients, although many complained of paresthesias and indefinite pains in the extremities. This form of neuritis occurring in old age (senile polyneuritis), described first by Oppenheim in 1893, is not produced by any of the usual causes of neuritis, and is characterized by a gradual onset and insidious course, without acute symptoms: The sensory symptoms are insignificant, chiefly paresthetic, while the motor paralysis is also slight, affecting the distal rather than the proximal portions of the extremities. In advanced cases some muscular atrophy may be present.

Heart.—That symptoms indicative of cardiac pathology should be found in association with arteriosclerosis is to be expected, but the frequency with which they occurred was rather higher than I had supposed. Nine cases in the series were excluded because of an imperfect cardiac study. Of the remaining ninety-one, cardiac murmurs were recorded in twenty-four per cent. of the patients. A mitral systolic murmur was found in eighteen cases—a mitral diastolic murmur in one case; aortic systolic murmur in one case and a double aortic murmur in one case. One patient presented double aortic and mitral murmurs. The aortic second sound was accentuated in twenty per cent.; distinct evidence of cardiac enlargement in 19.8 per cent., and muscle weakness was recorded in 47.3 per cent.

Kidneys.—The average specific gravity of the urines was 1017. Fourteen were below 1015 and four above 1025. Albumin was present in varying amounts in thirty-two per cent. of the cases, and casts, chiefly hyaline and granular, in twenty-five per cent. In no instance was sugar found in the urine. Therefore, between one-fourth and one-third of the patients presented some evidence of kidney involvement.

Arteriosclerotic insanity.—In addition to the mild mental symptoms mentioned as a common finding in cerebral arteriosclerosis, one finds in text books on mental disease certain psychoses described under the headings of presenile delusional insanity, arteriosclerotic insanity, senile dementia, senile delirium, senile paranoia, etc., which, when analyzed, are but variations of the same theme.

Common to all is a gradually progressive mental deterioration, with amnesia for recent events, due to lack of impressibility. There is ready mental fatigue, a general slowing of mental processes, with diminished energy and capacity for mental work and inability to acquire new facts or ideas. Not only is all work performed less well, but accuracy is affected and judgment becomes impaired. Emotional instability is noted, the patients manifesting irritability or passing readily from one mood to another, from laughter to tears. They are lacking in sympathy, become indifferent to their friends and relatives, and often careless in their habits.

As the dementia progresses, the amnesia becomes more marked; happenings of yesterday, or even within the last few hours are forgotten; the same questions are asked, the same stories repeated. Yet incidents and facts relating to early life may still be recalled along the old and well worn memory paths of the years, not easily effaced. They become self-centred, their personal comfort or whims, often childish, assuming primary importance. The friends of a life time or the relatives who have cared for them are ignored and their senile affections not infrequently transferred to a recent acquaintance, perhaps a nurse or attendant. New wills may be made in favor of the latest favorite, excluding those who by blood ties and moral right should inherit their property. Or, the dementia may be colored by delusions of suspicion, of infidelity, or of persecution. Auditory and visual hallucinations may appear and finally clouding of consciousness and disorientation may be added. Insomnia and nocturnal restlessness become marked. Sooner or later the various physical symptoms are added; the tottering gait, the shaking hands, incontinence, ataxia, paralysis, etc., until death mercifully ends the chapter.

If evidence of general arteriosclerosis is present and the mental manifestations are accompanied by symptoms resulting from cerebral vascular disease, as vertigo, syncope, convulsions, and other conditions, we use the term arteriosclerotic insanity. Progressive mental deterioration, occurring in an old person without much associated physical evidence of arteriosclerosis, would be a simple senile dementia. When delusions appear early and the dementia and physical deterioration are relatively slight, the psychosis becomes a presenile delusional lunacy or a senile paranoia. On the other hand, we should remember that extensive cerebral arteriosclerosis may be present without any associated mental impairment.

Shakespeare has given us a remarkably accurate and pathetic picture of senile dementia in the tragedy of King Lear. Are not childishness, confusion, disorientation, amnesia and dementia all shown in these few lines?

> Pray, do not mock me.
> I am a very foolish fond old man,
> Fourscore and upward, not an hour more or less;
> And, to deal plainly,
> I fear I am not in my perfect mind.
> Methinks I should know you and know this man;
> Yet I am doubtful; for I am mainly ignorant
> What place this is, and all the skill I have
> Remembers not these garments, nor I know not
> Where I did lodge last night. Do not laugh at me;
> For, as I am a man, I think this lady
> To be my child Cordelia.

Observations on Lumbar Puncture in Neurosyphilis*

By A. BENSON CANNON, M.D.,
New York,
Instructor of Dermatology and Syphilology, College of Physicians and Surgeons, Columbia University.

It is probably impossible to determine exactly when the first lumbar puncture was made, or by whom, but Quincke (1), in 1891, has the distinction of presenting the earliest lumbar puncture technic for clinical use. He was also the first to suggest lumbar puncture as a possible aid in diagnosis, though only in relation to pressure and volume. In 1902, Milian, Crouzon and Paris (2) stressed the wisdom of doing lumbar puncture in all syphilitics suffering with headache, even in the absence of other symptoms pointing to involvement of the nervous system. In 1906, Wassermann and Plaut (3) discovered that the cerebrospinal fluid of paretics reacted positively to the Wassermann test. Following such investigation on the neurological side of syphilis, this test was placed on a practical basis when Hauptmann and Hössli (4), working in conjunction with Nonne, demonstrated that the amount of spinal fluid, 0.2 c. c., the same used for blood tests, was not sufficient to give the reaction for cases with central nervous system involvement, and increased the amount to 1.0 c. c. Since that time the Wassermann test has been greatly enhanced in value by titrating the volume of fluid from 0.1 to two c. c. Beginning with these experimenters, the lumbar puncture as a diagnostic procedure has obtained more and more recognition. Without the aid afforded by lumbar puncture our knowledge of the processes in the nervous system would remain vague and obscure. In 1912, Swift and Ellis (5) published their invaluable paper on the treatment of neurosyphilis with salvarsanized serum.

In order to do a lumbar puncture, one must have a certain amount of skill and a degree of self confidence in addition to a suitable needle and a knowledge of the essential principles involved. The operation is usually carried out in the following way: The patient lies on his side with the thighs flexed on the abdomen, the head as close to the knees as possible, the arm beneath the body extended so that the patient's weight rests on the back of the shoulder and scapula. The spine is thus arched toward the operator. The space between the third and fourth lumbar spines is usually selected for puncture, although the one between the second and third, the fourth and fifth spines, or the fifth spine and sacrum may exceptionally be used. A line drawn between the highest point of the iliac crest and the lumbar vertebra corresponds to the space between the third and fourth lumbar spines. The centre of this space is then marked with iodine or by indentation with the finger nail, and the area sterilized and anesthetized with novocaine or else frozen with ethyl chloride.

The operator grasps the handle of the needle firmly between the terminal phalanx of his thumb, index and, perhaps, the middle finger, obtains his alignment, and having the patient take a deep breath, thrusts the needle straight in. If the spine is not completely flexed, he bears slightly upward. If he does not hold the needle too rigidly, it takes the course of least resistance. If bone is encountered, he withdraws slightly and redirects his point. When the dura is pierced, a lessened opposition is readily transmitted to the fingers, and sometimes a sharp snap is felt and heard. It is usually necessary to penetrate a distance of one to three inches, or even more, in an adult, and two or more cm. in a child, this, of course, depending on the build and obesity of the patient.

On reaching the subarachnoid space, the operator removes the trocar and allows the fluid to flow, turning the needle slightly if the fluid runs too slowly or if blood is mixed with the fluid. He occasionally has to introduce or withdraw the needle about an eighth of an inch, or often asks the patient to count, finding that this increases the flow. With the aid of a local anesthetic (two per cent. novocaine), the procedure, if skillfully done, will cause the patient no pain.

Reference has often been made to the dangers of doing lumbar puncture in those cases with cerebral tumors, especially where the tumor is located at the base of the brain. Nonne (6) mentions several instances of sudden death following puncture under these conditions. In questionable cases of this kind, the opinion of a neurologist is advisable.

After the lumbar puncture, the patient is placed in a dorsal recumbent position, with the head lowered. Two hours later he is allowed to turn, but is kept in bed from twenty-four to forty-eight hours and is given all the fluids he can comfortably take.

The symptoms resulting from lumbar puncture vary from a slight headache to a throbbing occipital and frontal headache with vertigo, general weakness, nausea, vomiting and collapse. Symptoms are usually absent while the patient is in the recumbent position, but immediately recur on his assuming an erect posture, medication giving little or no relief. A week's rest in bed usually restores the patient to normal, although the symptoms may persist for more than six weeks. Occasionally, a patient will have sharp pain in the frontal and occipital region upon coughing or sneezing for two to four months after a lumbar puncture.

Symptoms occur with about the same frequency in those with negative serology as in those with active neurosyphilis. After a puncture, women and neurotic patients are especially likely to develop symptoms which are not always relieved by a recumbent position, even with the head a great deal lower than the feet.

The frequency and character of the symptoms following spinal puncture have given rise to wide discussion and investigation. At one time, it was generally believed that the severity of the reaction was in direct ratio to the amount of fluid removed. In support of this theory it was pointed out that where less than ten c. c. of fluid were removed, there was less likelihood of a reaction, while with the removal of larger quantities, from fifteen to forty-five c. c., severe symptoms, and even death followed. Quincke estimated the spinal fluid pressure before and after puncture, and reported that the fall in pressure bore no relation to the amount of fluid removed. One and five tenths c. c. caused a drop of eighty-five mm. in one case, and eighteen c. c. a drop of only ninety-five mm. in another case, and he asked, as a result of his experiments, "What is to guide us in the amount to remove?"

---

*Read before the Medical Society of the County of New York, December 23, 1922.

MacRoberts (7) has published some interesting observations in regard to the etiological factors involved in postpuncture headaches. He believes the headaches are produced by a leakage of fluid through the hole left by the needle when it is withdrawn from the dura and arachnoid. In support of this belief, he cites an instance in which although no fluid was removed a typical severe lumbar puncture developed headache, lasting eight days. He argues that it is ridiculous to think, if the headaches are due to the eight or ten c. c. of fluid usually withdrawn for diagnostic purposes, they would continue for days, when it is generally accepted that the amount of fluid formed by the choroid plexus in twenty-four hours greatly exceeds that withdrawn.

With MacRobert's theory in mind, I punctured thirty-four nonsyphilitics, twenty men and fourteen women, none of whom had ever been punctured before. These were punctured in the sitting position, and in each case I made certain the membranes were entered by gradually removing the trocar until fluid appeared, reinserting the trocar, and withdrawing the needle. No fluid was removed. The patients were kept up, and allowed to move about as usual. I carefully questioned each patient, finding that only four of the thirty-four complained of any symptoms whatever. Two of the men had slight frontal headaches the following night while in bed, the headaches lasting two to three hours and being unrelated to posture. One of these men, a leper, had received an injection of chaulmoogra oil just before the puncture, the injection having been followed by headache in a previous instance. The other man had erysipelas of the face, but was not subject to headaches. Two women also had mild headaches, not influenced by posture, nor sufficiently severe to prevent their being up. One of these had a discharging middle ear, with a secondary dermatitis of the skin, and was subject to frequent similar headaches. The other woman had received electrodesiccation for lupus vulgaris of the face immediately after the puncture.

Experimenting in an endeavor to prevent the occurrence of lumbar puncture headaches, I followed a suggestion by Doctor J. E. Moore, using a technic similar to that employed by Corbus and his associates in the treatment of neurosyphilis, substituting, however, sterile distilled water for the hypertonic salt solution. I felt if a hypertonic salt solution could cause an osmosis of the lymph fluid into the blood vessels and an increased intravascular pressure, that the reverse would take place if a hypotonic solution were used. I have often noticed where the usual amount of fluid for diagnostic purposes was withdrawn under pressure, a headache practically never developed. I punctured fifteen cases, each puncture being preceded five hours before by an intravenous injection of two hundred c. c. of sterile distilled water. The experiments resulted in my finding that there was no apparent increase in the intraspinal fluid pressure and no appreciable reduction in the severity of the headaches.

It has been my experience to encounter few lumbar puncture headaches following intraspinal treatment with serum; in fact, considering the large number of patients I have had under observation during the past few years, their absence has been striking. It has occurred to me that the explanation of their rare appearance might lie in the fact that such a large amount of serum is injected, as compared with the small quantity of fluid removed for examination at the time of treatment. I have been interested to observe that lumbar puncture headaches are less likely to occur with each succeeding puncture, and when they do follow they are less severe.

Since the introduction of subarachnoid therapy in the treatment of neurosyphilis, various modifications of the Swift-Ellis method have been tried, but no new procedure has been so universally employed, nor has any been followed by results so uniformly successful.

Intraspinal therapy as originally suggested by Swift and Ellis consisted of the administration of an intravenous salvarsan; bleeding of the patient an hour later; centrifugalizing the blood and placing it on ice for twenty-four hours; pipetting off the serum; adding normal salt solution; incubating at 57½° for one half hour, and cooling to body heat before injection.

The addition of normal saline to the serum before introduction into the subarachnoid space, as formerly used by Swift and Ellis, has been discontinued, and now the undiluted serum is added to a quantity of spinal fluid withdrawn in the receptacle. The method of adding neosalvarsan directly to the spinal fluid, as employed by Ravaut (8), Nonne and others, was soon discarded because of the cord irritation produced.

The unfortunate results of this method were largely responsible for the discredit of intraspinal therapy in this and other countries. Ogilvie (9) modified the method in question by adding a definite quantity of faintly alkanized salvarsan solution (one tenth to one half milligram) to serum, which he incubated at 55° centigrade. The procedure of Ogilvie, while an improvement over the method of adding neosalvarsan to the spinal fluid, is also one attended with some danger of cord irritation if the salvarsan is not added with great care. It is easy to add an amount of the drug which may cause cord irritation, with bladder and rectal paralysis.

Recently, Corbus and his associates (10) suggested a new method, having for its object increased osmotic properties of the blood plasma, produced by intravenous injection of a hypertonic salt solution, followed six hours later by 0.9 grams of neosalvarsan given intravenously. The authors assert that the arsenic penetration is as constant or better than in any system yet described, a slight trace to 0.01 milligram per c. c. being found in all cases except in two, ninety-three per cent. of the total number of cases. No serological results were given.

Several methods of intraspinal medication have been brought forward in which preparations of mercury are used. Sir Victor Horsley (11) advocated subarachnoid lavage, while Sicard (12) used injections of mercuric chloride, 0.1 milligram, and novocaine in saline, 0.5 milligram.

Byrnes (13) devised a treatment consisting of an albuminate of mercury solution in serum, prepared by mixing .013 to .026 milligram of mercuric chloride with twelve c. c. of human serum, and eighteen cubic centimeters of normal saline, and incubating this at 56°. The reactions that follow the use of mercury intraspinally are much more severe than those following the Swift-Ellis method, and, according to Keidel and Moore (14), the results are not so good.

In the work which I have been doing in association with Dr. Fordyce during the past seven years, we have tried various methods of intraspinal therapy and have discarded all in favor of the Swift-Ellis. We found that one tenth to one half mg. of arsphenamine could be safely added to serum withdrawn one hour after intravenous injection, but on reduction of the bleeding time to one half hour, in many of the cases there developed evidences of slight cord irritation. Since we reduced the bleeding time the results have been just as good with Swift-Ellis alone, and practically free from injurious effects.

After the lumbar puncture is done, as described in a preceding paragraph, five to ten c. c. of fluid are reserved for examination, allowing thirty to forty cubic centimeters to drain into the gravity cylinder, into which is also slowly added the serum. The cylinder is elevated and the fluid runs gradually into the subarachnoid space. Two or three times as much fluid is introduced intraspinally as is removed; thus an increased intraspinal pressure is produced. If the fluid is allowed to flow in too rapidly the patient will complain of gradually increasing pain in the coccygeal region, usually accompanied by a viselike constriction in the chest, difficult breathing, cyanosis, and weak intermittent pulse.

The reaction following a careful introduction of the serum varies from no symptoms to a mild or severe headache, shooting pains through the extremities, and occasionally nausea, vomiting and temperature of 99° to 102°. The headache is probably due to the irritating serum, or perhaps to increased intraspinal pressure and, in contrast to the typical lumbar puncture headache, is either not at all influenced by position, or else somewhat alleviated by an erect posture. The reaction ordinarily subsides in less than twenty-four hours, rarely necessitating morphine.

A course of treatment consists of six intraspinal injections, the first five of which are given at two week intervals, and the sixth at a three to four weeks' interval. With patients presenting pronounced posterior column degeneration, evidenced by ataxia, bladder and rectal incontinence, anesthesia and paresthesia in the lower extremities, the intervals between treatments should be lengthened to three to six weeks. We find that from one to twelve courses are necessary before a negative spinal fluid is obtained, the number of injections required naturally depending on the type of case. Each course of treatment is followed by a two to three months' rest.

While all lesions of syphilis have as their etiological basis the Spirochaeta pallida and have a more or less common pathological picture, the character of the medication depends upon the location and extent of the process. By means of repeated lumbar punctures, it has been almost definitely established that infection of the nervous system occurs in the secondary period of the disease, when the blood and lymph are saturated with the organisms. In this stage it is not unusual to see patients who while receiving active intravenous treatment, combined with mercury, show clinical and serological evidences of meningitis. While the meningitis in some instances may yield to further routine treatment, it is more usual to find the condition in the central nervous system progressing in spite of such medication. Here the intraspinal treatment meets its most rapid response.

Meningitis in this secondary period of syphilis can be cured by relatively fewer injections than an analagous condition in later stages of the disease.

We do not advocate intraspinal medication for patients of advanced age (sixty or above), nor for those with marked cardiac or renal disease. Advanced paresis is seldom benefitted, and, especially in those cases with marked depression or exaltation, treatment is often followed by an exaggeration of the symptoms.

Cerebral endarteritis, associated with evidences of an accompanying meningitis, often shows marked temporary improvement, but is subject to relapses depending on the degree of vessel involvement or destruction.

In early tabes and tertiary cerebrospinal meningitis of a few to many years' duration, as manifested by changes in the pupillary and deep reflexes, with either a slight or marked increase in the cell count and globulin test, a strongly positive Wassermann with high dilutions and a luetic curve, the Swift-Ellis treatment, while necessarily prolonged, frequently results in a remarkable functional restoration and a negative fluid. In cases of early or moderately advanced optic atrophy with basilar meningitis, we are often able to arrest the atrophy and secure a negative spinal fluid, with preservation of the existing vision. By the method in question, early paretics frequently show rapid clinical improvement, a reduction in the cell count and in the intensity of the globulin reaction, but we are rarely able to produce any change in the Wassermann and Gold Sol tests.

While recognizing that remissions of longer or shorter duration are frequently met with in general paresis, we believe the rapid temporary improvement which occurs in many of these cases, especially those with a high cell count in the spinal fluid, can only be ascribed to the treatment in question. Such induced remissions may continue from several months to two or three years.

Both neurologists and syphilologists recognize the similarity between general paresis and meningovascular syphilis. It is advisable, therefore, to give all patients with a doubtful diagnosis the benefit of intraspinal treatment. We are frequently astonished by the rapid and permanent results which follow combined intravenous and intraspinal therapy in patients who present the symptoms of clinical and serological paresis.

It has been definitely shown that in a certain percentage of cases treated with salvarsan alone, no arsenic penetration takes place in the spinal fluid. In my work with Dr. Fordyce, we have seen numerous patients with a history of repeated courses of salvarsan and mercury, yet with a persistence of clinical symptoms and positive findings in the spinal fluid. We have treated these cases intraspinally, and usually have seen them respond with marked clinical and serological improvement, and not infrequently with complete cure. We are therefore convinced, after an experience of years, that intraspinal medication should be given a very definite place among other methods of therapeutics. It should, however, never be employed without a thorough knowledge of the technic, and without proper laboratory facilities.

Case I.—Syphilitic meningitis. Male, aged thirty-two. Chancre in November, 1916, followed by a generalized rash and sore throat. Treatment was begun soon after appearance of the secondaries. Two months later there developed almost constant severe throbbing rightsided headache. Spinal fluid examination in May, 1917, was said to show 104 cells and weakly positive globulin, Wasserman and gold sol tests. The fluid was reported negative following three intraspinal treatments. The headache did not entirely disappear, however, and after a few months became almost unbearable. He also suffered with insomnia, loss of appetite and weight, and frequent attacks of motor aphasia. Sometimes he wandered about for several hours in a dazed condition. Patient was first seen November 20, 1917, when he complained of severe headache, nervousness and insomnia. On November 26th he became excitable, violent, and developed a delirium for several days, during which time he had to be restrained.

CEREBROSPINAL FLUID.

2/9/18	1	—	—with 2.0c.c.	0000,000,000	—

Treatment from November 23, 1917, to February 9, 1918. Eight intravenous injections of salvarsan, seven intraspinal injections (Swift-Ellis), sixteen injections of mercury salicylate. After three intravenous and two intraspinal injections the patient's mental condition entirely cleared and headache disappeared. A recent report from him states that he feels unusually well both mentally and physically and is able to attend to his work without difficulty.

Case II.—Cerebrospinal syphilis. Male, aged thirty-six, chancre in 1904. Since April, 1918, extremely nervous, excitable, talkative, and unable to sleep. For three weeks, wildly insane and grandiose. Patient had received since April, 1918, fourteen salvarsan injections intravenously, and twelve injections of mercury. Examination showed: pupils oval in shape, right greater than left, both reacting sluggishly to light; nystagmus; present, drooping of left eyelid; left side of face slightly drawn; right patellar and ankle jerks absent; patient grandiose and keenly excited.

9/22/21	1	—	—with 2.0c.c.	1112100000	—

Treatment from December 10, 1918, to September 22, 1921. Forty-four intravenous injections of salvarsan, thirty-three intraspinal injections (Swift-Ellis), sixty-one injections of soluble mercury.

For the first three months of treatment patient continued wildly insane. Following this he gradually became normal and has remained so to the present time. For three years he has been the head of a large contracting company and does his work well. His general health is splendid. The patient was again punctured August 28, 1922, and showed a normal spinal fluid and negative blood.

Case III.—Tabes, male, aged twenty-eight, initial lesion and secondaries denied, gonorrhea in 1907. In 1917 gumma of the left great toe and numbness of left foot. This attack was followed in a few weeks by numbness in right foot and severe shooting pains in the stomach, bowels and rectum, accompanied by frequent stools. Similar attacks repeatedly since. When first seen, June 28, 1919, he complained of gradually increasing ataxia, and difficulty in voiding urine. Sexual power absent for eight months. Frequent attacks of blurred vision with fainting, and severe shooting pains in legs for six months. In 1918 patient had three intravenous injections of salvarsan, one injection of mercury and six mercury rubs.

Examination showed: Irregular pupils, unequal in size; right eye 6 m.m. and left 4 m.m., both fixed to light; right arm reflexes greater than left; abdominal, epigastric, patellar and ankle reflexes absent; patient unable to stand without holding on to something, or to walk without assistance of two canes; wide area of anesthesia around chest.

8/12/22	2	v. ft. tr.	—with 2.0c.c.	1111000000	—

Treatment from June 23, 1919, to August 10, 1922, twenty-three intravenous injections of salvarsan, nineteen intraspinal injections (Swift-Ellis), fifteen mercury injections.

Patient is free from pain; has regained sexual power; has no bladder weakness; his ataxia is now scarcely noticeable, and he is able to walk several miles each day.

Case IV.—Optic atrophy, male, aged thirty-eight. Chancre in 1911. In May, 1918, vision in right eye became impaired, failing entirely by December, 1918. At this time vision in left eye began to fail. When first seen on February 14, 1919, patient complained that he had been nervous, forgetful and irritable for two years, suffering also every few months with fainting attacks accompanied by nausea. He had received twenty injections of gray oil in 1911, and ten injections each succeeding year. He had four intravenous salvarsans in 1918.

Examination showed: right pupil 5 m.m. in size, left 7 m.m.; total blindness in right eye, vision of 20/30 in left eye and contraction of the fields of vision; optic atrophy in both eyes; left arm reflexes, cremasteric, and knee jerk greater than right; A_2 sound greater than P_2 and accentuated; blood pressure 132/90.

CEREBROSPINAL FLUID.

6/25/21	1	—	—with 2.0c.c.	0000000000	—

Treatment from February 18, 1919, to June 25, 1921, fourteen intravenous injections of salvarsan, twelve intraspinal injections (Swift-Ellis), forty-four insoluble mercury injections, potassium iodide at intervals.

Patient is entirely free from nervousness, irritability, forgetfulness and fainting attacks; has gained in weight, and general health is much better; his vision has remained stationary.

Case V.—General paresis, male, aged forty-five. Initial lesion and gonorrhea in 1903. No symptoms until about June, 1917, when wife and friends began to notice complete change in patient's mental condition. Very forgetful; very extravagant; perverted sexual desires.

Examination showed: irregular pupils, right greater than left, and both stationary to light; arm, knee and ankle reflexes hyperactive, the right more so than the left; delusions; scanning speech.

CEREBROSPINAL FLUID.

Date	cells	globulin	Wassermann	gold sol	serum
9/15/17	80	4+	4+to 0.2c.c.	5555542000	4+
8/4/20	4	±	4 to 0.4c.c.	5555432100	4+

Treatment from February 18, 1919, to August 4, 1920, forty-four intravenous injections of salvarsan, thirty-six intraspinal injections (Swift-Ellis), seventy-seven injections of mercury.

Patient's mental condition gradually cleared under treatment and after six months he was able to resume his work. In August, 1920, three years later, he again began to show evidence of mental deterioration, becoming completely insane in February, 1922, when he was committed to an institution.

CONCLUSIONS.

Headaches following the removal of the cerebrospinal fluid are not due to leakage of fluid through the hole left by the lumbar puncture needle. Experiments to prevent postpuncture headaches have, so far, proved unsuccessful.

Lumbar puncture headches follow intraspinal treatment with serum, provided an increased intraspinal pressure is produced by injecting a much greater quantity of serum than the fluid removed. Patients are less likely to have reactions with each successive puncture after the first. We have obtained better results in treating neurosyphilis with the Swift-Ellis method than with any other we have tried.

A course of intraspinal medication consists of six treatments given at two to six week intervals, the intervals as well as the total number of treatments depending upon the type of case.

We do not advocate intraspinal therapy for people of advanced age, for those with marked cardiac or renal disease, or advanced paresis, or for tabetics with evidence of pronounced nerve root degeneration.

Many cases of neurosyphilis are clinically and serologically cured by intraspinal medication, where prolonged and consistent treatment with salvarsan, mercury and iodides has failed.

Visceral Neurology in Relation to Clinical Medicine*

By JOSHUA H. LEINER, M.D.,
Associate Attending Neurologist, Lebanon Hospital,
New York.

The manifestations of life's phenomena are primarily due to reflexes. This physiological law is present in the lowest forms, and is apparent in the highest types, although greatly complicated. Life, therefore, is one reflex after another, be it psychic, somatic (central nervous system type) or vicerovegetative in response. Should there arise abnormal interplay, outstanding features of either system become manifest, leading or portraying abnormal physiology. It is desired in this paper to stress clinical phenomena in a broad manner made apparent by implication of the vegetative nervous system, which controls visceral function. A study of visceral neurology is of great aid in reaching a correct diagnosis. It will aid them to visualize the pathways and mechanisms of the abnormal processes, and make them think of the body as an entity rather than the part suspected of disease as sequestered and autonomous.

The two large vegetative nerves of the body are the extended vagus and the sympathetic system, the latter being connected through spinal segmentation with the somatic or central nervous system, which can elucidate hidden visceral disease by superficial clinical phenomena.

This is brought about through the medium of reflexes, either pointing to the, 1, subcutaneous tissue or skin, as in segmental paresthesias, together with vasomotor and pilomotor response, and 2, by the muscular system as a defense mechanism with its attending rigidities, or if the condition be chronic leading to, 3, trophic disturbances—with its wasting of skin, subcutaneous tissue and muscle, and 4, where through complicated reflexes distant structures are involved.

To correlate this dual nervous system with the viscera in the manifestations of abnormal phenomena, one must accept in part at least the pharmacodynamic divisions established experimentally by Eppinger, Hesse, Higier, and others. Again one must bear in mind certain embryoanatomical considerations in attempting to map out the neurological fields of affected viscera. The viscera you will recollect were drawn downwards in the abdominal cavity during their embryological developmental period. There is, however, a fixed and constant specific spinal segment supply through definite connector neurones, which gives rise to visceromotor or viscerotrophic disturbance when affected. For example, if we take the female generative organs, although located in the pelvis, have their segmental connection as high up as the tenth dorsal segment. We know further from the study of primitive vertebræ, where pure segmental innervation reaches its highest development,

---

*Read before the New York Physicians' Association, May 23, 1923.

that the deep underlying viscera are innervated by the same spinal segment, as the skin muscle area, directly covering it. Bearing this in mind we can readily understand how we were built up segment on segment, each level having a more or less autonomous nervous system; later developments leading to correlation as exemplified in the brain stem, basal ganglia, and finally in the formation of the end brain.

The system counteracting the sympathetic is the vagus. This supplies most of the viscera. Its function is anabolic, storing up energy, while the sympathic tends to drive its mechanism for the consumption of energy. This mechanism also comes into play when the organism is in danger of attack, the defense mechanism operating through the thyroadrenal system so well shown by Cannon.

It follows that each of the viscera receives fibres from each of these systems, and connected through afferent pathways with the somatic nervous system, which reflexly through efferent spinal nerve fibres can show phenomena at certain bodily levels—motor, sensory or trophic.

Viscera on the whole are insensitive to pain; exceptions are the ducts leading out of viscera, the genital organs and hollow viscus. It can be stated as a general rule that as long as the viscera are normal no pain is felt. Whether pain is at all felt in viscera is a disputed question. Mackenzie's view is that when pressure is made on an inflamed organ through the abdominal wall, the pain is due to a hyperalgesia affecting the overlying wall or tissues. He shows further, that the organ may be displaced, but the area of pain is constant; then, again, the area of pain extends often beyond the anatomical limits of the organ.

CLINICAL PHENOMENA AND THEIR INTERPRETATION.

Acute involvement manifests itself reflexly in muscle spasms, a defense mechanism to protect the deep seated pathological process. This is well shown in an acute inflamed appendix, peritonitis, gallbladder and in ucer of the stomach. There is also an alteration in the cutaneous sensations, i. e., paresthesias and hyperesthesia. In pathological states one can often map out belts of hyperesthesia. The fifth dorsal to the twelfth covers the abdominal viscera, particularly the fifth to the ninth. The latter segments cover the stomach, particularly the sixth to the seventh, well exemplified in the rigidity of the left upper rectus muscle. It is important to remember that the pancreas is covered by the same segments. The referred pain anteriorly is in the epigastrium and posteriorly between the two scapula. The small intestine is covered from the fifth dorsal to the ninth dorsal, mostly the eighth or ninth dorsal. The appendix is innervated from the tenth thoracic to the first lumbar, producing in acute inflammatory conditions a reflex rigidity, through the transversalis and the right oblique muscles, and also involving in the visceromotor reflex the psoas. Although these sympathetic manifestations in gastric involvement are shown by visceromotor and viscerosensory signs, the vagus system is also implicated. For example, if there should be present a peptic ulcer, then phenomena pointing to that system is shown by nausea, vomiting, a hyperchlorhydria and an increased motility of the stomach. The reflex pains are mediated as stated through the sixth and seventh dorsal segment, and felt in the epigastrium or to the left of the median line, about this level. Clinically the genito-urinary apparatus shows a large number of reflexes involving the vagus system particularly. Recent reports by Bartrina and also Lanzilotta are instructive.

In chronic visceral disease Pottinger has done a large amount of work, and his observations on tuberculous intestinal ulceration of the small intestine and ascending colon, and in fact the study of tuberculosis in general stamps him as a keen clinician.

In the classic case of pulmonary tuberculosis viscerotrophic signs become manifest. The flat pectoral muscles become atrophied on the same side as the lesion, as well as the skin and subcutaneous tissue. This reflex trophomotor phenomena if we can call it a reflex, is in all probability due to a constant bombardment of viscerosensory impulses pouring into the spinal cord, disturbing not only function, but also nutrition of the anterior nerve cells, that supply the skeletal system. The law of nervous thresholds holds good here, i. e., the synapses can be easily spanned, and we find that the other muscles of the neck and shoulder girdle on that side are often atrophied, such as the sternocleidomastoid, the scalenii and others.

It is in the realm of pure reflex clinical medicine that vegetative neurology has its greatest sway and interest. The fifth cranial nerve or trigeminous is intimately connected with the vagus, which you will remember is made up of three nuclei, in the medulla the visceral, nucleus ambiguous (motor) and a sensory nucleus in the long fasciculous solitarius. With this fact in mind one can readily see the possibility of a great number of clinical reflex diseases and symptoms.

Let us take ordinary eye strain for example; this is often accompanied by vagal stimulation, and it also holds good for nasal conditions as in nasal polyps, where we see gastrointestinal involvement, with its anorexia, often nausea, and even vomiting, hyperchlorhydria, hypermotility, often constipation, and its accompanying train of symptoms of toxic origin, leading to headaches; and as a viscious circle involve the fifth cranial nerve which supplies the meninges, which give us one type of migraine. Pressure on the eyeballs leading to the well known phenomena of bradycardia. The anginal pain of angina pectoris is due to a viscersensory response mediating as preganglionic white medullated fibres from the first dorsal to the fifth or sixth and as postganglionic from the stellate ganglion. The first and second spinal segments enter into the brachial plexus formation, and supply the inner side of the arm, which explains the mechanism of the pain transmission to the arm in this disease. This is a sympathetic pathway. On the other hand a vagus stimulation of cardiac origin is seen in the cardiac asthma where the bronchioles are affected, reflexly. In pulmonary tuberculosis the phrenic of that side is called into play, producing limited diaphragmatic motility, into which often enter the action of the intercostals. The costal portion of the diaphragm is innervated by the lower segments of the thoracic region. Artificial pneumothorax is a rational step forward in healing chronic pulmonary tuberculosis copying from Nature's methods.

It is beyond the scope of this paper to go into the subject minutely. Sherrington, Head, Pottinger, Mackenzie and Ross have done a vast amount of work in this field. The future teaching of medicine must go along lines where elucidation and interpretation of clinical systems must have a definite basis. Heretofore a disease was studied regardless of the individual, and if the patient did not show classic symptoms, we had no explanations.

Years ago in the neurological clinics, seventy-five per cent. of the patients treated were called neurasthenics; today we look upon certain functional disturbances as having a base in finer biochemical bodily changes through the glands of internal secretion and the vegetative nervous system. In other words, the title and name functional neurology should be supplanted in my opinion by vegetative neurology. I desire to mention only the affective state, fear. Modern physiology has given us a clue as to the manner of operation. Cannon's work is enlightening in this respect. Fear as an etiological adjuvant enters into the production of diabetes, exophthalmic goitre, epilepsy, paralysis agitans and a host of organic and psychoneurotic states, brought about through the mechanism of the vegetative nervous system.

Again in diseases due to anaphylaxis there is a direct connection with the vegetative nervous system. Most of its manifestations point to a parasympathetic drive. Whereas the toxic conditions usually lead to a stimulation of the sympathetic system, which means a thyroadrenal drive with its consequent increased metabolism, increased heart beat, rise in temperature, lack of bodily secretions, constipation and so on.

In health these two systems, together with the glands of internal secretion, balance themselves, a state that leads to wellbeing both mental and physical. We are, however, for certain inherent reasons, either potential vagotonics or sympathicotonics. If, therefore, some disease or situation should overtake us then the system that we have a leaning towards will undoubtedly assert itself.

Of interest in this connection is the recently conducted investigation by Van Wagenen. He conducted the Goetsch test on a group of perfectly healthy students at Cornell University, and it is interesting to note that twenty per cent. showed themselves potential sympathicotonics.

Vagotonics on the other hand may not have all their segments involved clinically. I have been searching for years for a clean cut vagotonic, and have not as yet found a pure type, conforming to the type that Eppinger, Hesse and others write about. The following three cases are vagotonics, with certain outstanding segmental involvement.

CASE I.—1539, L. J., male, aged fifty, Austrian, leather worker. His chief complaint was a marked distress in the epigastrium and precordium with nausea, which incapacitated him to such an extent that he could not work. In fact, he could not rise from his chair when the attack occurred.

This dated back two and a half years, when he suddenly began to vomit while at work. There was an interesting history that the day previous a relative who lived with him came home with what seemed an attack of influenza. This frightened him badly, for people during this period of the epidemic were dying all around him and he felt his children would contract it. Because of his distress and vomiting he was taken to one of the large hospitals in the city, where a laparotomy was done, a gastroenterostomy, and an appendectomy with no relief.

Physical examination showed his heart, lungs and abdominal viscera normal. His somatic nervous system showed that aside from a slight nystagmoid movement in the left lateral plane with an exaggeration of his deep reflexes, he was normal. The urine was normal. A diagnosis that his symptoms pointed to an involvement at the level of his autonomic system was made, and he was placed on atropine. One month later he was able to go to work; the first time in two years. Whenever we stopped his atropine medication his symptoms returned.

Blood examination revealed an increase in clotting time, together with an eosinophilia. Nearly a year and a half has passed and this patient has felt well and gone back to work. An illuminating notation on his clinical card is noted—September 16, 1922, to September 30, 1922, the patient complained again of his old symptoms. During this period his atropine medication was stopped to again study the blood picture. As a result his symptoms returned again.

CASE II.—E. S., aged sixty, born in Russia, tailor. He had had attacks of pain in the back of his head and a peculiar pressure pain in rectum, either coming at night or in the morning. His father died of asthma. He was married forty years and his wife had nine children. All were apparently well. Venereal history was denied. The bowels were constipated. This illness began ten years ago. He had been to various hospitals and institutions, but failed to get any relief. He was operated on at Bellevue Hospital by a well known surgeon for a prostatectomy and bladder operation.

Aside from having a slightly palpable liver his physical examination showed him normal. His pupils are unequal, right greater than left. The right pupil was slightly irregular in outline and showed a slight corneal opacity. Otherwise there was nothing pointing to his somatic nervous system. The Wassermann was negative.

The mucosa of his sigmoid was normal. His rectum showed some internal hemorrhoids, and a dry and granular mucosa.

The first time he was brought to the clinic he was crying bitterly from pain, begging to be relieved from his terrible pressure in the rectum and severe pain in the back of his neck. His attack had already lasted over thirty-six hours; during this time there was no moment of relief during the day or night. Examination at this time showed a flushed face, pupils showing nothing characteristic, but he was perspiring profusely.

He was placed on atropine. His attacks gradually left. They were limited to one attack a week for a short time, and then they disappeared entirely. It is an interesting clinical finding to note that his constipation cleared up with the administration of the atropine.

While atropine relieves spastic constipation the exact mechanism is not entirely clear. The sympathetic system acts on the circular fibres of the intestine, constricting them, and releases the sphincters, whereas the vagus system acts reversely. The action is probably on the intestine causing a release of the circular fibres.

This patient for five months was entirely free from pain, and had become a useful member of society and gone back to work.

Case III.—B. J., female, aged forty-six, married, born in Russia. Her chief complaints were: 1, constipation; 2, frequency of urination; 3, marked abdominal distention; 4, pain in the abdomen, lower right quadrant, and 5, vasomotor disturbances—heat flashes, sweating, etc. In addition to these symptoms there occurred periods when the patient suddenly began to feel a marked pressure in the region of the epigastrium, as if there was a large socalled lump, followed by belching, and often vomiting, which only showed mucus. These attacks usually were preceded by frequency of urination, and pain in the lower abdomen as mentioned.

The previous history revealed that this woman had a gynecological operation three years previous, following which she had her menstrual periods but twice, and then they had ceased entirely. Since the operation the patient suffered more than she had immediately following the operation. This patient undoubtedly had an endocrine imbalance and pituitary extracts benefitted her greatly, however, not to the extent that the atropine did. The relief with atropine is in both the bulbar autonomic and in the sacral divisions. This patient did not show any eosinophilia, but there was a long clotting time.

In conclusion, I would like to stress the importance of a knowledge of the vegetative nervous system in the practice of medicine either as a specialist or as a general practitioner. Surgeons in particular should bear in mind this syndrome. That vagotonia is a symptom complex, and belongs to the domain of general medicine. That it is rarely seen involving all segments, and that it exists more often as segmental or circumscribed vagotonia. That segmental or circumscribed vagotonia should be considered as vagal crises—not due to lues in this instance.

The Röntgen Signs of Increased Intracranial Pressure*

By LEWIS J. FRIEDMAN, M.D.,
New York,
Assistant Radiologist Bellevue Hospital. Radiotherapist Stuyvesant Polyclinic.

The diagnosis of an increase in intracranial pressure is applied to a characteristic local or general alteration of the intracranial shadow. While this condition is usually a sign of some organic disturbance, it is occasionally congenital in its origin and apparently of no serious significance.

In order to understand the normal radiographic appearance of the skull, it would be well to briefly describe the normal anatomical characteristics. The primitive development of the skull occurs mostly from intermembranous ossification and usually from one or several centres for each piece of skull. Eventually narrow bands of membrane remain which correspond to sutures seen in later life (1).

The outer and inner compact layers form the tables of the skull, between which is the cancellous bone—the diploe. In the adult, the outer table varies in thickness between one and three mm., while the inner table may be 0.5 to two mm. Aside from the individual and racial characteristics, the thickness of the skull varies between three and eight mm. The thickness is not uniform throughout the skull, but is much thinner in the frontal and temporal regions than in the occipital, which part measures as much as ten mm., particularly so in the negro.

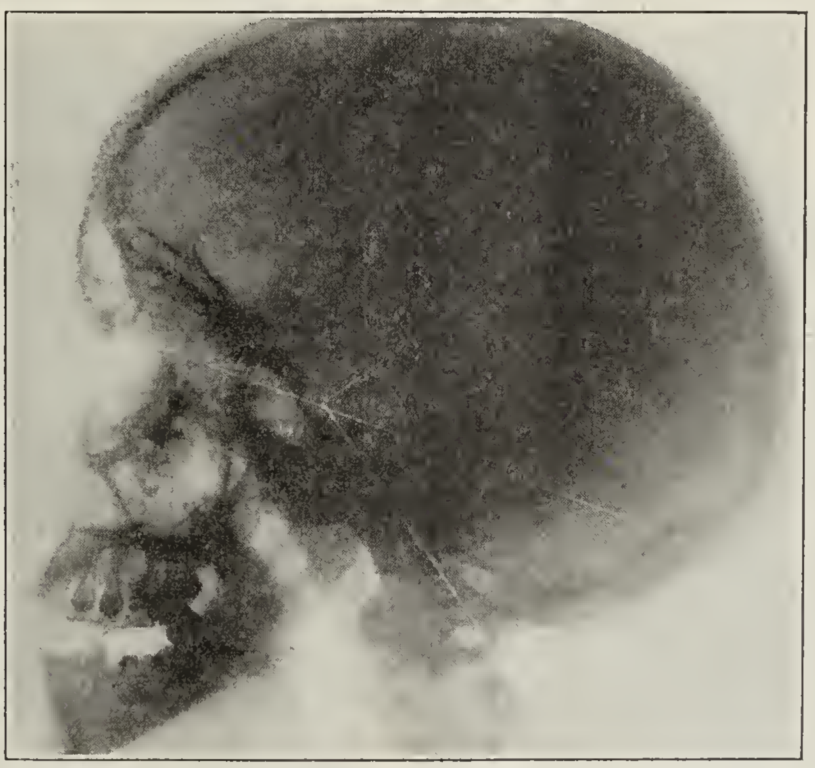

Fig. 1.—Normal skull. Subject aged nineteen. Notice homogeneous shadow of brain area. Angle of Welcker 148°.

The outer surface of the skull is rarely of smooth contour and is traversed laterally by ridges, and medially and sagitally by sutures formed by the frontal, parietal, and occipital bones, respectively. The sutures in the anterior portion of the skull become synostosed earlier than those in the posterior, and the lambdoid suture may never become completely synostosed.

Most of the cranial sutures are dentated, serrated, or a combination of both. The squamoparietal suture, termed the sutura squamosa, is formed by an overlapping of the two contiguous bones by broad beveled margins. There are several Wormian bones which are occasionally seen at the anterior extremity of the sagital suture and in the course of the lambdoid sutures.

The diploe is channeled in the adult by numerous tortuous canals which lodge the deploic veins—the frontal, the anterior temporal, the posterior temporal, and occipital deploic veins. In the aged, these veins eventually intercommunicate with each other. The emissary veins, the most important of which are the mastoid, parietal, and occipital, communicate with the intracranial sinuses. The internal surface of the skull presents depressions for the convolutions of the brain and grooves for the meningeal arteries, sinuses of the skull, and depressions for the pacchionian bodies in the superior region of the vertex.

---

*From the X Ray Department, Bellevue Hospital, Dr. I. Seth Hirsch, Director. Read before the New York Physicians' Association, May 23, 1923.

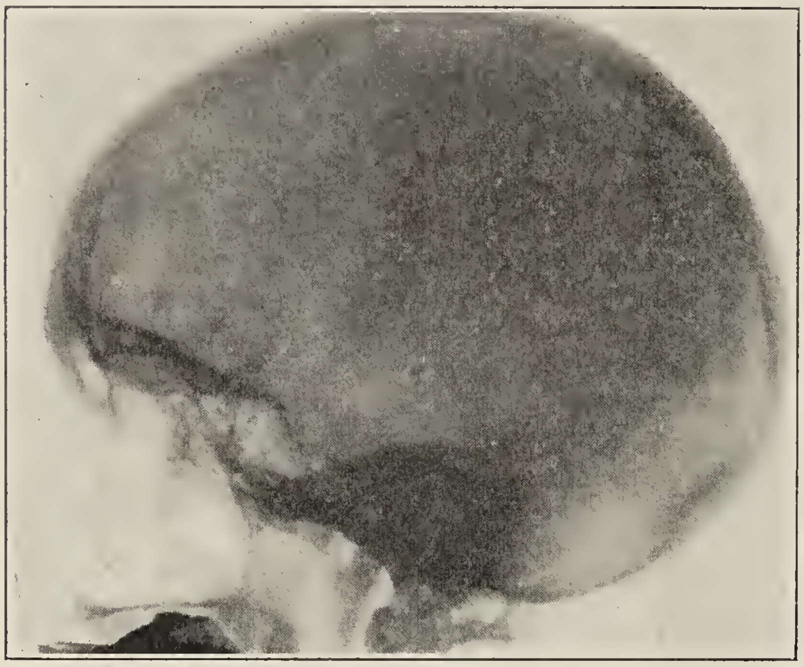

Fig. 2.—Adult normal skull; aged sixty. Notice accentuation of grooves for the middle meningeal artery.

The röntgenological appearance of the normal skull: While the skiagraph of a normal skull coincides completely with the anatomical characteristics, the shadow of the internal and external bony elements are superimposed on each other and makes a complex picture. The skull is considered as casting a dense shadow or otherwise described as an illuminated area which is fairly homogeneous. (See Fig. 1.) There are four areas on the skiagraph of a skull which appear more illuminated than the midfield. These are over the vertex, the base, the region of the anterior fontanel, and the region of the torcular herophili.

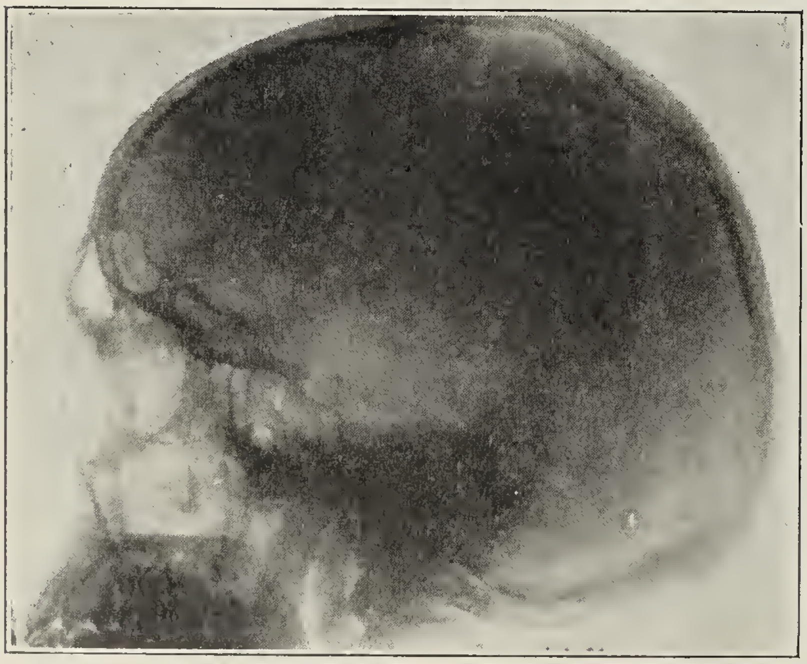

Fig. 3.—Case I.—Notice illuminated area in postcoronal region. See Fig. 4.

The physical reason for the presence of these areas is the thinness of the skull, the presence of venous sinuses, and aqueducts. The pacchionian bodies can often be seen in the postcoronal region; while the large venous acqueduct causes the illuminated area in the occipital region.

A groove for the middle meningeal artery can be visualized and usually begins about one and a half cm. anterior to the anterior clinoid process extending upward to the vertex almost parallel and posterior to the coronal suture. About two and a half cm. from its origin, this groove bifurcates, the parallel portion accommodating the middle meningeal, while the other portion of this groove runs backward traversing the temporoparietal bone for the lodgment of the posterior branch of the artery. (See Fig. 2.)

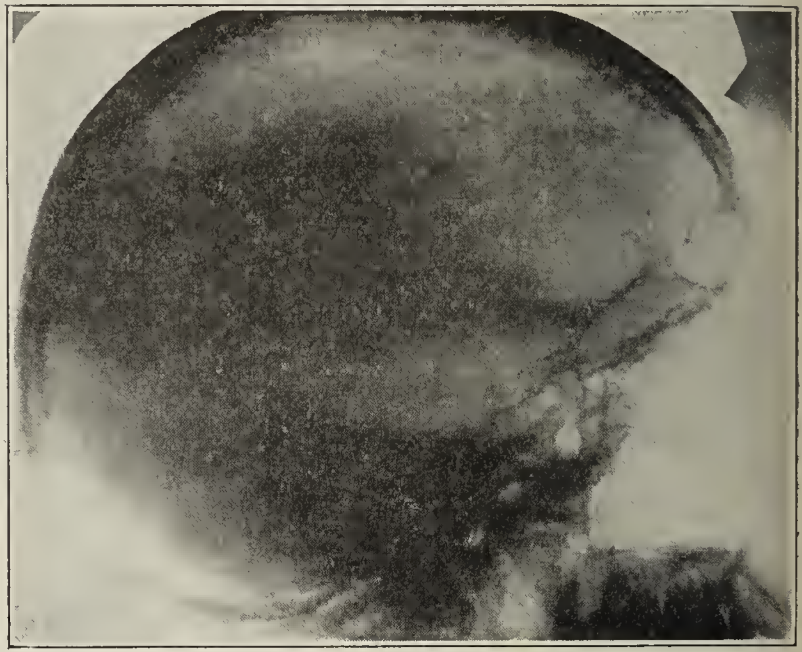

Fig. 4.—Same patient as Fig. 3. Radiograph taken eight weeks later.

The pineal body is at times visualized as a small sclerotic area in the temporal region about three or four cm. perpendicularly above the auricular canal.

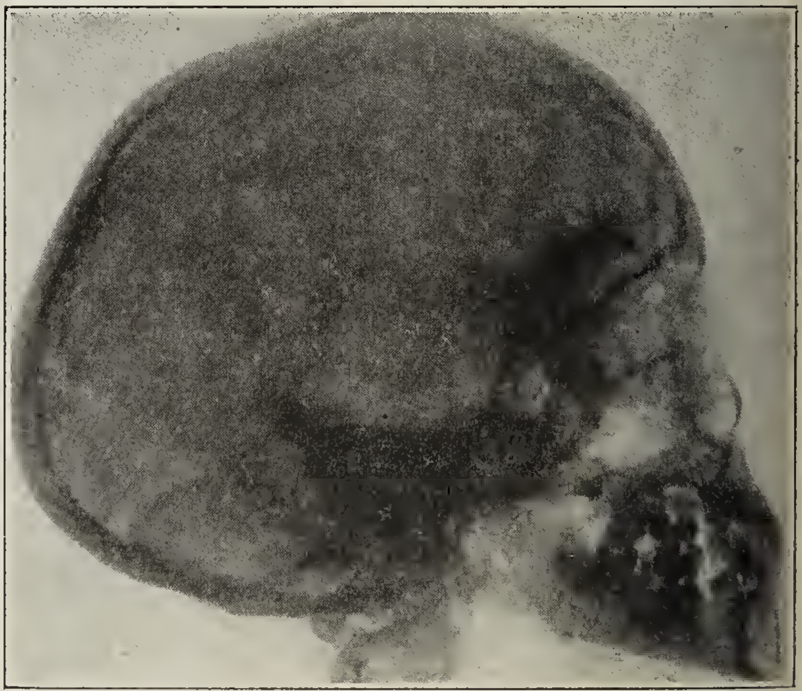

Fig. 5.—Case II.—See Fig. 6.

The symptoms of increased intracranial pressure may be, 1, local; 2, general, localizing or special (2). These symptoms depend, of course, on the type of intracranial pressure existing, and will be outlined below under the various types.

In the examination of about three thousand cases at Bellevue Hospital of which 750 were examined for evidences of injury or pathology, evidences of intracranial pressure have been observed in about seventy-five per cent. of the cases. The patients were referred with the following clinical diagnosis: Fractured skull, concussion of the brain, foreign bodies in brain, dyspituitarism, brain tumor, Paget's disease, microcephalus, hydrocephalus, temporosphenoidal abscess, epidural abscess, epilepsy, Mongolian idiocy, mental deficiency, acromegaly, syphilis, multiple myelomata, and metastatic carcinoma.

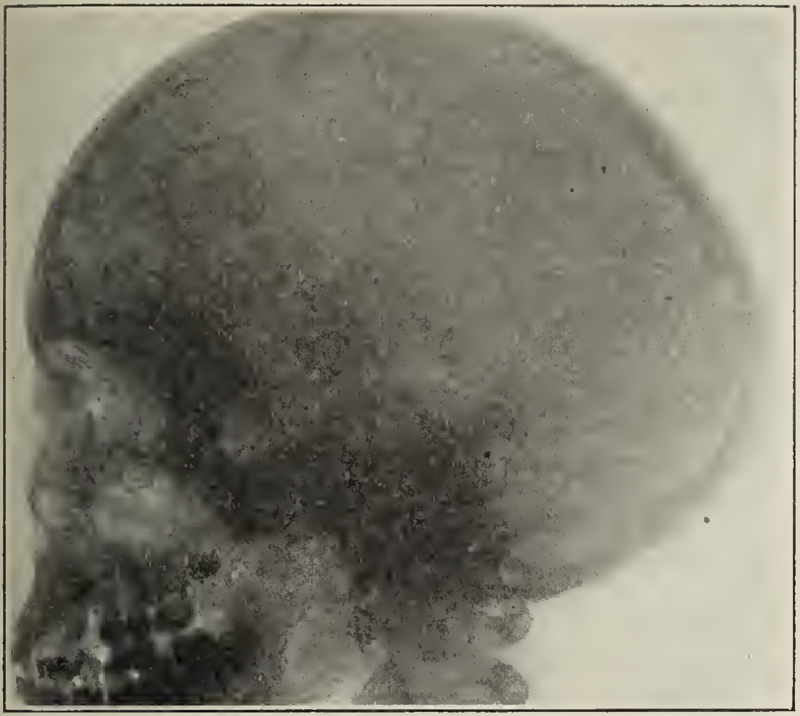

Fig. 6.—Same patient as in Fig. 5. Radiograph taken seven weeks later. Notice the appearance of the brain area.

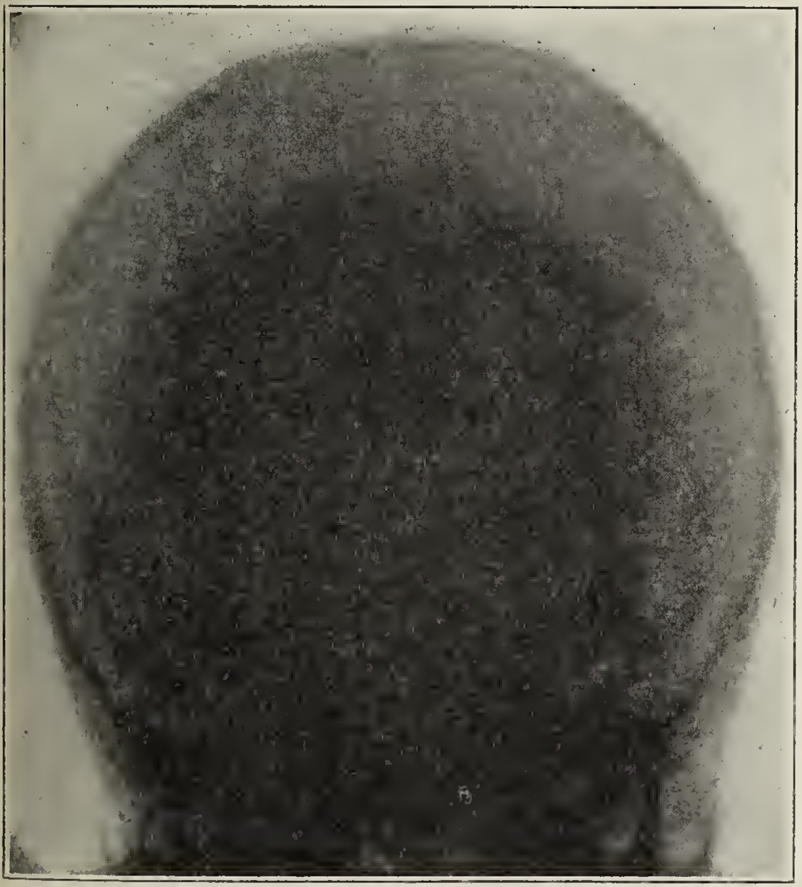

Fig. 7.—Showing a serrated fracture of the left parietal. Notice mottling as evidence of increased pressure, and accentuation of the left lateral sinus shadow.

The usual routine for examination of patients referred with the history of trauma was to radiograph the base, and skiagraph the right and left lateral views of the skull. Cases referred with a history of pathology, the additional sella turcica examination was made and also examination of the hands for dystrophic disturbances. Reexamination of the head was resorted to at intervals of from five to ten weeks after the original examination and comparison made of the first and last radiographs taken.

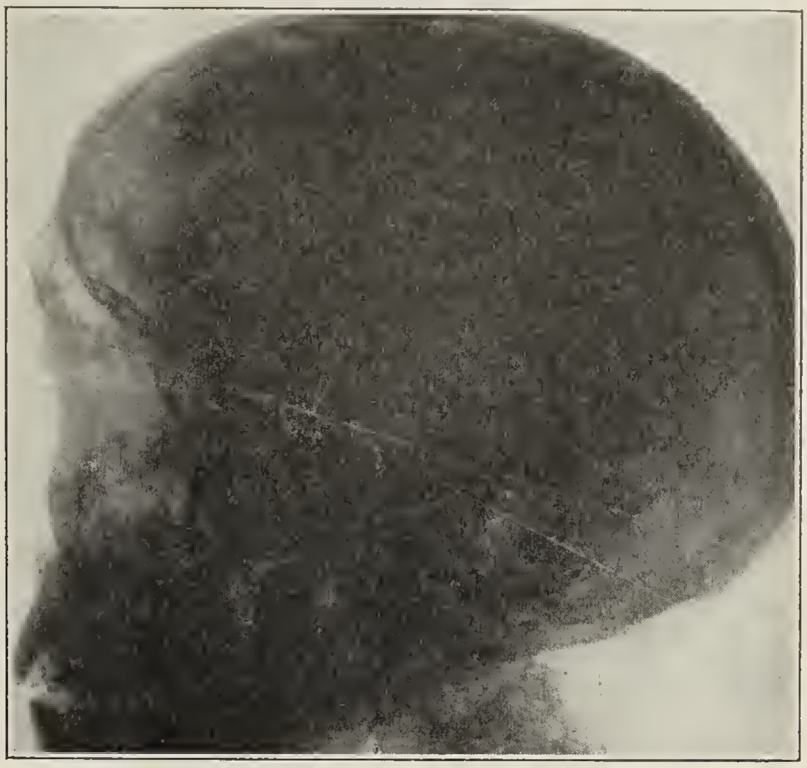

Fig. 8.—Adult aged thirty. Notice retarded cerebral development; evidence of convolutional impressions; and increase of angle of Welcker to 170°. Clinically considered, subnormal mentality.

The röntgen signs of increased intracranial pressure: Röntgenologically, intracranial pressure can be essentially divided into acute, subacute, and chronic. The acute type can readily be interpreted by observing a peculiar mottling of the skull field, better described as areas of increased illumination with intervening spaces of the normal brain shadow. (See Figs. 5 and 7.) This appearance justifies the diagnosis of a diffuse mild form of edema of the brain. This edema may arise not only from injury, but from laceration of the brain which according to Von Bergmann (3) occurs in concussion. Every case in which lumbar puncture was performed

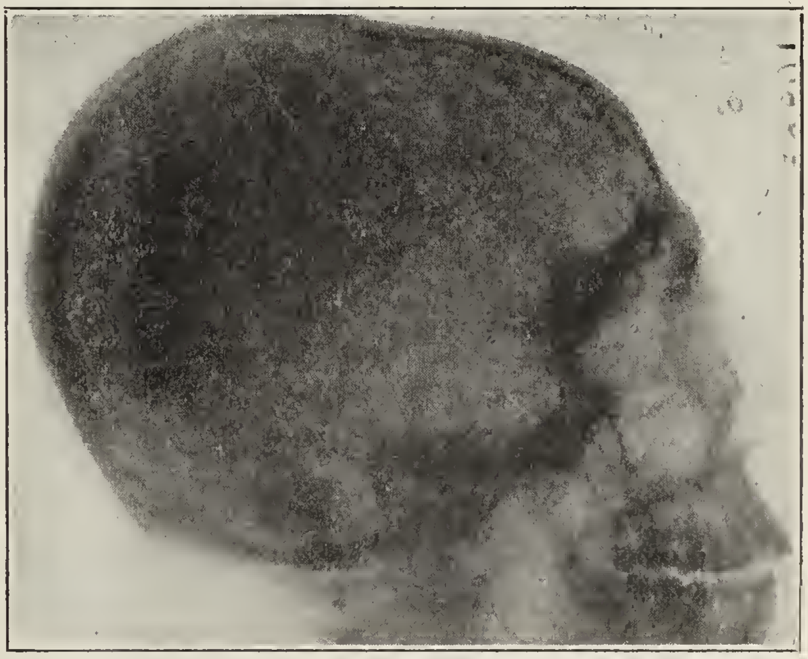

Fig. 9.—Case IV.—Anomalous skull showing intracranial pressure; depression of the middle fossa; increased angle of Welcker.

shortly after an injury, bloody spinal fluid was found even though there was no evidence of fracture.

The acute type is observed subsequent to cranial injury. In the absence of evidence of fracture of the skull, the presence of mottling of the skull field indicates the existence of concussion of the brain. The clinical findings invariably warrant and substantiate the interpretation. This mottling is usually absent in cases of extensive fractures, particularly so if they are compound in character. This can be readily explained by the relief of tension and the escape of fluid. The clinical symptoms of acute intracranial pressure are naturally of the depressive type and usually transient, although the x ray findings may persist for a period after complete recovery.

Rupture of a vascular twig in the epidural space produces the characteristic shadow of a small haematoma accompanied by the usual pressure symptoms, although no diffused intracranial pressure signs may be visualized. As an illustration, I shall report Case I.

Case I.—Male, aged thirty-seven, sustained an injury to the vertex by being struck with a blunt instrument. Clinically, the symptoms were unmistakably those of severe concussion. The radiograph (Fig. 3) visualized an area of increased illumination immediately posterior to the coronal suture. When reexamined about eight weeks later, the epidural hematoma had been entirely absorbed.

It is often necessary to recognize evidences of acute intracranial pressure even though they may be superimposed on the shadows produced by convolutional impressions of the congenital type. The following is an illustration of this condition.

Case II.—(Figs. 5-6.) The signs of acute intracranial pressure were visualized in a boy fourteen years of age who had incidentally a microcephalic head with crescentic osteoporotic areas of convolutional impressions of the congenital type. The acute concussion produced an exaggeration of mottling of the brain area. The disappearance of this condition was readily apparent when reradiographed about seven weeks later.

The subacute type of intracranial pressure is observed at a more remote period after an accident and is accompanied by certain subjective symptoms such as headaches and vertigo. Röntgenologically, the presence of subacute intracranial pressure is also recognized by the presence of mottling though not as extensive as seen in the acute form. The differential diagnosis of the two depends considerably upon the clinical history, date of injury, objective signs—though the latter may not always be present.

CHRONIC INTRACRANIAL PRESSURE.

The recognition of chronic intracranial pressure is probably the most important as an aid in the diagnosis of brain pathology. The chronic type can be divided into two forms—the congenital and acquired.

The congnital type is sometimes seen in apparently normal individuals or those of subnormal mentality. It has been observed in oxycephalic and microcephalic heads.

The acquired type has been observed in cases of injury, epilepsy, and occasionally in brain tumor. The röntgenological characteristics of chronic intracranial pressure are evidences of crescentic osteoporotic areas of the inner table of the skull which may be general or confined to the frontal, parietal, or occipital areas. Sutherland describes the evidences of intracranial pressure as seen in oxycephalic heads as "Putty finger impressions due to an atrophy of the inner table and attributed to the pressure of the convolutions (4)."

Accentuation of the grooves for the intracranial vessels is another form in which intracranial pressure may be observed. The subjective signs are at times obscure and can only be elicited by careful neurological examination. At times, however, there are certain objective and subjective signs: Asymmetry of the pupils, incoordination, headaches, optic disc changes (5), local or generalized convulsions, vertigo, vomiting, nystagmus, dyplopia, psychic disturbances, inferior mentality, insanity, and other signs. The signs simulating increased intracranial pressure which have been observed in the congenital type are also accompanied by certain changes in the shape of the skull such as exaggerated brachycephalus, oxycephalus, microcephalus, and etc. To illustrate the effect of injury to a head showing the congenital type of increased pressure, I shall report Case III.

Case III.—Child, aged eight, sustained a head injury two years prior to the x ray examination. The skiagraph visualized a moderate sized head with exaggerated convolutional impressions throughout, more marked in the cerebral area. The most prominent subjective symptom was the uncontrollable irritability and homicidal and suicidal tendencies.

Case IV.—Fig. 9 shows skiagraph of J. W., colored male, who was recently found guilty of manslaughter, but in view of the röntgenologic findings and neurological examination, he was adjudged insane and is now confined in an institution. This type of skull showing the exaggerated convolutional impressions (intracranial pressure) is of the congenital type, the clinical significance of which was a homicidal form of insanity (paranoiac).

SUMMARY.

Evidences of acute intracranial pressure are a distinct entity and occur in ninety per cent. of concussions. It is visualized in eighty per cent. of fractures. (See Fig. 7.)

The visualization of mild convolutional impressions in a person suffering from headaches, vertigo, etc., after an injury can be considered as due to trauma.

The presence of convolutional impressions in a child is usually congenital and in the absence of untoward symptoms may be ignored.

The presence of convolutional impressions in unruly children or those showing signs of inferior mentality speaks for a poor prognosis.

Intracranial lesions, or neoplasms rarely show evidences of intracranial pressure. Tumors of the hypophysis and cerebellar pontine angle produce a characteristic absorption of the clinoids and depression of the middle fossa, but no generalized evidence of intracranial pressure.

Aside from the clinical importance of demonstrating the effect of chronic intracranial pressure, the recognition of this condition is frequently a forensic necessity.

The author's references will appear in his reprints.

Tumors of the Cerebellum

By P. K. MENZIES, M.B., (Toronto,) F.A.C.S.,

Syracuse, N. Y.

In the cerebellum, as in other parts of the brain, various forms of new growths are found. Those predominating, however, are tubercule, gummata, and the sarcomatous types of tumor. In the large series of Cushing and Elsberg, approximately two-thirds were either gliomata or gliomatous in structure.

In the brain as a whole, tumors occur with about the same frequency at all ages, although rarely after the sixth decade of life. In childhood, fifty per cent. of all brain tumors are cerebellar, while in later life the proportion drops to about twenty-five per cent. One would naturally think that the type of new growth would vary with the age of incidence, and this is found to be the case. Under twenty years, one-half are tuberculous, and the remainder gliomata, endotheliomata and sarcomata, occurring in the order named. Between twenty and forty, gummata are the most common, with gliomata second and sarcomata third. After forty, sarcomata and carcinomata predominate. Sarcoma is usually primary, while carcinoma is invariably secondary to the condition elsewhere.

Sex seems to exert some influence on the type as tumors occur twice as frequently in the male, with the exception of sarcoma which attacks both sexes equally. In some cases, heredity seems to play a part, and in a small percentage, the new growth would seem to result from a cranial injury.

The function of the cerebellum is a threefold one: 1, that of organizing the higher automatic and psychoreflex movements, 2, that of enabling the person to maintain his equilibrium and relations in space, and 3, that of giving tonus and synergy to the body muscles. Pagano, some twenty years ago, proved by animal experimentation that stimulation of one lateral lobe of the cerebellum produced motor phenomena. These varied in intensity from simple contraction of one muscle group of a limb, causing it to assume a certain fixed attitude, up to violent convulsions. He found that there were definite cerebellar zones corresponding to groups of muscles on the same side of the body. There was also a rotation of the body on its longitudinal axis, which occurred constantly from the side of excitation toward the opposite side. When he extirpated the contralateral motor area of the cerebral cortex the muscular contractions on the same side ceased, showing that the contraction was accomplished through the motor cortex of the opposite side. However, there then occurred a rotation of the body in the opposite direction, showing that the cerebellum had some action on the motor cortex of the same side, and thus on the muscles of the opposite side of the body. When both cerebral motor areas were completely extirpated, the motor phenomena were entirely abolished. When the anterior portion of the vermis was stimulated, there was an irresistible tendency to raise the head and fall backward, while irritation of the posterior portion of the vermis produced a tendency to fall forward.

The cerebellum is constantly receiving impressions from the eye, the vestibular apparatus, and the muscles of the body through the spinal cord, also in all probability from the skin. As a result of these, it elaborates efferent impulses to the central nuclei, the cerebral cortex and, through them, to the body musculature. Static equilibrium is maintained subconsciously, if not wholly unconsciously. This reflex arc passes through the cerebellum, the red nucleus, the corpora quadrigemina, the nuclei of Dieter and Bechterew, and the nuclei of the pons.

The process of correlation in voluntary movement is complex. The cerebral cortex sends impulses to the cerebellum at the same time as it sends impulses to the cord. The former pass through the crux, pons and middle cerebellar peduncle. The cerebellar efferent impulses pass through the superior cerebellar peduncle, red nucleus and optic thalamus, informing the cerebrum of all modifications in the muscular apparatus. At the same time, the necessary muscle tone is being maintained by efferent impulses from the central cerebellar ganglia.

As increased intracranial tension is an early symptom in brain tumor, let us for a moment consider the cerebrospinal fluid and its circulation. Secreted by the choroid plexus in the lateral ventricles, it passes from the third to the fourth ventricle through the aqueduct of Sylvius. Through the foramina of Magendie and Luschka in the roof of the fourth ventricle, it reaches the external surface of the brain, bathes the nervous tissue, and is finally absorbed in the subarachnoid spaces of the brain and cord. It has been proven experimentally that little if any absorption takes place internally. If the aqueduct of Sylvius is blocked by the introduction of a foreign body or if finely divided animal charcoal is injected into the third ventricle, internal hydrocephalus immediately occurs.

When we consider the function of the cerebellum and its location under the tentorium, it is not difficult to understand why the earliest evidence of tumor may be either mechanical, due to increased intracranial pressure, or functional due to interference with muscle control. In any subtentorial tumor there is likely to be early pressure on the fourth ventricle, and consequent interference with the flow of cerebrospinal fluid into the subarachnoid spaces. This may be gradual but will eventually give rise to the cardinal symptoms of headache, vomiting and choked disc. Headache may be due either to the increased pressure or direct irritation of the dura, which is supplied by branches of the fifth cranial nerve. The vomiting, usually projectile and without nausea, is caused in all probability by irritation of the medullary centre. It is commonly the earliest symptom, and childhood is frequently taken as an indication of stomach trouble. Choked disc, the most constant sign, is purely mechanical and is due to increased pressure along the optic nerve.

On the other hand, the earlier symptoms may be due to interference with cerebellar function. These commence with an ataxic stumbling gait, with general muscular weakness, especially in the lower extremities. Strabismus and nystagmus may occur early in the disease, with facial weakness on the same side as the lesion. As the disease progresses the patient tends to fall backward, or to one side, and may even fall over when sitting. Sudden vertigo is not uncommon and may go on to unconsciousness. So called cerebellar seizures occur, in which there are sudden short forced movements irregular and tonic in character, as opposed to the clonic movements in cerebral irritation. There is frequently a faulty coordination of those movements usually performed in unison, especially locomotion. Jerky movements of the hands are frequent. Cerebellar catalepsy may be present, and there is almost invariably a disturbance in the normal labyrinthine reactions.

As the disease progresses the intracranial pressure increases. Normally this varies between forty and one hundred and fifty millimetres of water, but in disease may increase to nine hundred millimetres of water. The mind becomes apathetic and sluggish. Blindness ensues with paralysis of the ocular muscles, while the pupils become dilated and fixed. The headache and vomiting decrease. The neck retracts and a positive Kernig may be present. The pulse, slow at first, becomes rapid as we get bulbar compression and finally paralysis.

In our diagnosis, we must first determine the presence of a tumor, then localize it, and finally try to determine what type of growth it may be. The progressive course of the disease, with the symptoms of headache, vomiting, choked disc, mental disturbances, the interference with muscle function, and local signs are all characteristic of brain tumor. Some of these, however, may be found in localized tuberculosis or syphilitic meningitis, lead poisoning, hysteria, internal hydrocephalus or abscess. A history of syphilis or tuberculosis, along with the age of the patient, helps us considerably, as do any signs of local tenderness, or the discovery of a new growth in another part of the body. A differential blood count helps to rule out the acute inflammatory conditions. Lumbar puncture and examination of the spinal fluid should rule out cases of acute meningitis and tuberculosis. A Wassermann of blood and spinal fluid is always indicated. As the great majority of cerebellar abscesses are due to middle ear infections a negative ear history and examination help to rule out that condition. The x ray may show a change in density of the brain, or a localized thinning of the skull, but in general is of little aid in tumors below the tentorium. At times percussion has given a duller note over the tumor, and in some cases noted by Ballance, there was a distinct bulging of the thinned out occiput over the tumor.

With tumor of the lateral lobe, we would expect to find ataxia and general muscular weakness, with diminished or lost reflexes on the side of the tumor, and a tendency to fall to that side. In the nystagmus, the eye movement tends to be slower and of greater amplitude on looking toward the side with the lesion, finer and more rapid on looking away from that side. If the tumor is in the vermis, there is greater loss of equilibrium, and a tendency to fall forward or backward rather than to the side. The great difficulty in accurate location, however, lies in the fact that in an encapsulated growth, pressure is transmitted and signs of irritation may occur at a considerable distance from the tumor itself.

In deciding what type of tumor is present, one must remember the frequency of tubercule in childhood. Often a solitary tubercule is present which exhibits all the characteristics of a tubercule elsewhere, and may reach a considerable size. Syphilomata are becoming less frequent, under the earlier and more efficient methods of treatment of the disease. They are usually associated with syphilis elsewhere, a meningitis or general arterial change. Usually they start growing in the pia, and may reach a considerable size. They are usually irregular in outline with a grayish periphery, and degenerated centre consisting of small round cells, spindle cells and disintegrated nervous tissue elements. Gliomata are the only tumors peculiar to nervous tissue found especially in the cerebellum. They constitute two-thirds of the adult tumors and are derived from the neuroglial cells supporting the brain, and not from the membranes or fibrous structures. They vary in size, may grow slowly or rapidly and are rarely encapsulated. Usually they have the appearance of congested or pale brain tissue with indefinite boundaries, and are often very vascular. The brain tissue is infiltrated and replaced by the tumor, the centre of which may undergo cystic degeneration, or in some cases a general disintegration. Microscopically they consist of small cells with intervening fine wavy fibrous prolongations. When the fibrous elements predominate, they are called fibrogliomata and when there is a preponderance of round cells, they are known as gliosarcomata.

Sarcomata exhibit a number of forms, each with its special characteristics. They may develop from the meninges, the vessel or nerve sheaths, or metastasize from sarcoma elsewhere. Both round and spindle cell types are found. They grow rapidly or slowly according to type, and not infrequently are encapsulated. The usual forms of degeneration occur. Certain slow growing types arise from the dura and contain calcareous deposits; these are called psammomata. These are white, gray or yellow in color, and microscopically show round cells, spindle cells and others of different types.

The endotheliomata originate from the endothelial tissues, often the meninges, are usually encapsulated, and if so are easily removed when found. Fibromata, enchondromata and lipomata are extremely rare. Osteomata are more frequent, but appear as calcareous plates in the dura or tentorium, and do not invade the brain itself. Carcinomata are rare and never primary in the brain. Echincoccic and cysticercus cysts are also rare. When found they are multiple, encapsulated and slow in growth. As they form in the ventricles or on the surface of the brain, they often produce no symptoms.

The prognosis in tumors of the cerebellum is always unfavorable. Tuberculosis and gummata may respond to treatment. Rarely does a tumor become encapsulated and undergo atrophy. The course of the disease is gradually progressive and the rapidity varies according to the type. Generally the symptoms become more pronounced till death supervenes in a year or two. It may occur within a month from the time the first symptoms are noted, while cases are on record which survived for eighteen years.

Medical treatment, with the above prognosis, is not very satisfactory. Tuberculosis is treated as elsewhere. A gumma may respond to treatment, and iodides have been known to benefit even nonsyphilitic cases. The ice cap is useful for headache, and the pain may be controlled by opiates. Lumbar puncture may be used to determine the intracranial pressure, but it is exceedingly dangerous to draw off much fluid in the presence of a subtentorial tumor, as the medulla is likely to be forced into the foramen magnum, and sudden death result.

Surgical treatment, while so frequently and rapidly fatal, offers the best chance in these cases. The cerebellum is more easily approached than many other portions of the brain, and brilliant results have been obtained, even where it was necessary to remove all of one cerebellar lobe. Even if the tumor cannot be localized, the patient should not be allowed to go blind for the lack of a decompression.

The most satisfactory approach to the cerebellum is through the crossbow incision of Cushing. The prominent boss on one side of the occipital bone is opened with trephine or Hudson drill, and the dura exposed. The opening is enlarged with a rongeur. If the tumor is apparent, the meninges are incised and the mass removed if possible. In cases where it is impossible to remove the whole tumor as in cases of an infiltrating type, the removal of a portion has been known to result in the atrophy of the remainder. If the tumor is not apparent, palpation may reveal its presence below the surface, when the intracranial pressure is not too great. Search should then be made with trocar and cannula, through an opening in the dura, as in a case of brain abscess. This is of help, however, only in those cases where the density of the tumor is greater than that of the brain, or where the tumor has undergone central cystic degeneration.

When the tumor is not found or is not removable, a decompression should be performed. The opposite boss of the occipital bone is removed and the ridge of bone in the midline removed carefully, on account of the midoccipital sinus and emissary veins. When the bone opening has been enlarged to a sufficient size, the median occipital sinus is divided between ligatures, and the dura excised from the area exposed by the bone opening. If possible the wound is closed without drainage. This decompression may save the patient's sight, lessen the severity of the symptoms, and allow of more accurate localization and operation at a later date.

The following case history will illustrate several features of cerebellar tumor, and some of the difficulties encountered in their diagnosis and treatment, especially in young children.

Case—R. M., aged two and a half years. Family history was negative for tuberculosis, syphilis or brain tumor. No history of middle ear trouble at any time. Apparently strong and healthy till one month before admission, when he commenced to vomit daily and was treated elsewhere for stomach trouble, with no success. On admission to hospital, examination showed a well nourished child, lying on back, fully extended, semiconscious, with head turned to the left. There was extreme flaccidity of both arms and legs, with least in left arm muscles. Reflexes: arm decreased, abdominal absent, patellar absent, right Babinski and Oppenheim, plantar flexion response on left, no clonus on either side. Horizontal nystagmus present. Sensory signs not demonstrable on account of coma. Head turned constantly to left and resisted passive turning to right. Rigidity of neck and upper spinal muscles, with occasional opisthotonus. Ataxia and stereognosis not determinable. Considerable purulent nasal secretion, and pus in the nasopharynx. Tonsils buried. Ears clear with retracted drums. Vestibular examination showed nystagmus to left with convergent squint. Eyelids kept closed. Pupils semidilated and responded to light. Both discs choked, more advanced on the left. No evidences of tubercule. Nystagmus, long component to left, unequal, left eye moving farther at times and at other times lagging on recovery. Movements not coordinated. Left eye convergent at times, other times divergent.

Temperature 99.2° F. pulse 104, respiration 22. Blood examination: red cells 3,500,000; white blood cells 16,800, polymorphonuclears 64 per cent., lymphocytes 34 per cent., eosinophiles 2 per cent.; hemoglobin 70 per cent. Blood taken for Wassermann. Lumbar puncture showed some increase in the intraspinal pressure. Fluid was clear and showed 9 cells per cmm. chiefly lymphocytes, also a slight increase in globulin. Urinalysis negative except for specific gravity of 1030.

Second day: Condition remained about the same. Took nourishment well. Cried out at times. X ray examination of head showed nothing abnormal. Left eye remained convergent. Pupils equal. Less nystagmus. Increase in choked disc.

Third day: Cried frequently, general condition the same. Lumbar puncture gave 12 cells per cmm. Wassermann negative. 11,200 white cells.

Fourth day: Child more quiet. Respirations 12 per minute. Left pupil slightly irregular and larger than the right. Left convergent strabismus when quiet. Slight nystagmus to left. No increase in choking of discs. Reflexes in right leg have disappeared.

Fifth day: Condition about the same. Respirations have dropped to ten per minute. Operation decided upon. Diagnosis: Cerebellar tumor, probably in left lateral lobe.

Operation: Through cross bow incision, dura over left lobe of cerebellum was exposed. Intradural pressure much increased, but no loss of pulsation. Left cerebellum explored with trocar and cannula. No fluid or abnormal resistance encountered. The trephine opening was enlarged to a diameter of three cm. The same was done on the right side, with no abnormal findings, and the two openings joined. The occipital sinus was ligated, and the dura excised. Hemorrhage was slight and easily controlled. After decompression, there was some herniation of the cerebellum through the opening. Wound was closed without drainage. The patient apparently withstood the operation well, but six hours after operation temperature and pulse commenced to rise, while the respirations became shallow and infrequent. After twelve hours the patient died, apparently from respiratory failure.

Autopsy findings.—A tumor was found in the right lobe of the cerebellum, at a depth of two centimetres from the exposed surface of the brain. It was three centimetres in diameter, and of the same consistency as the brain substance. It projected forward and inwards, and had exerted considerable deforming pressure on the right brachium of the pons. Its centre was yellow in color and degenerating, but not purulent. The margins were quite distinct but not encapsulated. A few small hemorrhagic points were found, due evidently to the cannula in exploration. The left cerebellum was normal, and there were no signs of meningeal irritation. The remainder of the brain was normal.

1. The diagnosis of cerebellar tumor is not usually difficult, but definite localization may be impossible.

2. It is important that every patient with persistent vomiting, especially in childhood, should have an examination of the eye grounds.

3. The course of the condition is often rapid, and the mortality very high under the most favorable conditions. Early diagnosis, however, is most essential.

4. Decompression at least should always be performed. The opening should be large enough to stabilize the abnormal intracranial pressure. If this is done, blindness is averted and a further opportunity is allowed for the more definite localization of the tumor.

Confused States Following Infections*

By IRVING J. SANDS, M.D.,
Brooklyn,
Instructor in Neurology, Columbia University; Associate Neurologist, Montefiore and Brooklyn Jewish Hospitals.

Periods of confusion, lasting from a few moments to several hours, are commonly encountered in people suffering from cerebral arteriosclerosis. These periods vary from mere momentary lapses of content of thought or mild momentary states of confusion, to complete disorientation and states of bewilderment lasting for several minutes or even for hours. These people may suddenly stop for one moment while holding a conversation and appear momentarily dazed; and then pick up their former trend of conversation. They may, however, be unable to resume their topic of discussion and inquire as to the subject about which they had just been talking.

Occasionally such lapse of consciousness may be associated with motor phenomena such as twitchings of some extremity, and they may experience sensory disturbances in the nature of paraesthesias in some part of the body. In the more serious cases, such lapses of consciousness are often associated with anxiety and considerable apprehension. Physical examination of such people will reveal evidence of cerebral arteriosclerosis and possibly of general arteriosclerosis as well. The blood pressure is, as a rule, high, and the urine frequently shows a low specific gravity and a faint trace of albumen. Mentally these people show a lowered mental tension, with emotional instability and occasional periods of irritability.

There recently came under our observation a group of cases who had been previously treated for general arteriosclerosis by their family physicians, and who, following some mild infection, showed marked changes in their behavior which necessitated observation in a psychopathic ward. These patients showed marked fear reactions, anxiety, visual and auditory hallucinations, and persecutory delusional trends. They were completely disoriented, and frequently misidentified those about them. Physically they showed a somewhat undernourished condition, heart showed poor action, and the blood pressure, however, was relatively low. The eye grounds showed evidences of arteriosclerosis, and the peripheral arteries were moderately thickened. The urine showed albumen, low specific gravity, and an occasional hyaline cast. There was, as a rule, no leucocytosis. Blood chemistry in these cases revealed nothing of significance. The tongue was dry, red, and deeply furrowed. The bowels were constipated. The deep reflexes were uniformly accentuated, and there were no pathological reflexes present. Sensation was, as a rule, intact. The cranial nerves revealed nothing pathological except for slightly irregular pupils which were sluggish in their reactions both to light and accommodation. The temperature rarely went above 100 and the pulse varied between 70 and 100.

They showed frequent outbursts of excitability which was due to marked fear and apprehension, resulting from their delusions and hallucinations. They would ask for protection from their imaginary enemies, and never were quite fully convinced that no harm would come to them even after repeated attempts at assurance on the part of the nurses and physicians that they would be fully protected.

After rest in bed, forced fluid intake, high colonic irrigation, the pathological mental states of these patients would, at the end of from one to two months, gradually clear up. The blood pressure returned to above 150, the tongue assumed a more normal appearance, heart action was stronger and general physical condition would be much improved. Mentally, they never showed full insight into their condition—they were amnesic for the acute period of their illness, but never seemed to fully appreciate that they had undergone a serious mental illness. Their entire recovery seemed to coincide with their steady rise in blood pressure to over 150, so that as soon as that point was reached a favorable termination would be prognosticated. The following cases will illustrate this condition.

Case I.—Male, aged forty-seven years, pharmacist by occupation, married. Admitted on April 18, 1922, being transferred from a private sanitarium. The family history was negative. The patient had been working quite steadily at his business and had rarely taken any real vacation. For several years he had consulted his private physician for high blood pressure which usually ran in the neighborhood of 200. At the same time he had had sugar in his urine.

---

*From the Psychopathic Service, Bellevue Hospital, N. Y. Read before the N. Y. Academy of Medicine, Section on Neurology and Psychiatry, April 10, 1923.

About three weeks prior to his admission, the patient had a few furuncles on the back of his neck, which, however, yielded to ordinary surgical treatment. He then became somewhat suspicious, thought people were trying to rob him and seemed morbidly fearful. He appeared quite irritable and quarrelsome. He got an idea that he could not go to bed, as he might die. He then became unreasonable, and unmanageable. He became physically weak. He was taken to a private hospital and there definite delusional trends developed; thought he was being doped to death by hypodermic injections; became resistive, and it was necessary to have him sent to the psychopathic wards of Bellevue Hospital. On admission the patient was quite confused, dazed and bewildered; he would not allow anyone to approach him; he was suspicious of everybody about him; was disoriented in all fields. He spoke at random; at times he would run out of bed apparently reacting to his hallucinatory experiences. Physically he showed a foul breath; red, dry tongue; markedly accentuated deep reflexes; heart sounds were rather feeble and distant; his urine showed a specific gravity of 1010; a faint trace of albumen, no sugar, a few epithelial cells and no casts; his pupils were somewhat irregular but reacted fairly well. His eye grounds showed definite arteriosclerotic changes. His blood Wassermann was negative. His blood chemistry showed N. P. N. 34 mg. per 100 c. c. of blood; sugar 145 mg. per 100 c. c. of blood; carbon dioxide 68. He had 9,000 white blood cells and 75 polymorphonuclears. Blood pressure 130/85

For three weeks the patient was confused, and at times excited. He spoke of cans of ether being thrown on him; was very suspicious of those about him; did not recognize his wife or child. He was restless during the night. At times he would break out into attacks of screaming or shouting, and it was found necessary to restrain him in bed. Occasionally he was incontinent. During this time frequent urine examinations showed a specific gravity of 1010 to 1020, moderate traces of albumen and occasional hyaline casts. His blood pressure varied from 130 to 140. His mental state then gradually began to clear; began to recognize the members of his family; complained of great sense of weakness, but never appreciated his real mental and physical state. His blood pressure gradually rose to above 150, and the general tone of his heart musculature improved. He slept fairly well and took his nourishment quite well. He was discharged on May 15, 1922, apparently recovered from his attack.

CASE II.—Male, aged sixty-four, white, married. Admitted May 18, 1922, with a history of having been confused and excited for three days. The family history was negative. The patient had always been of tense makeup, but of good habits; had worked for over twenty years with the gas company and had never had any difficulties. He had been receiving treatment from his family physician for high blood pressure. One month prior to his admission the patient had a general cold in the head, sneezed a good deal, had a running nose; then began to cough and at the end of a week took to bed. He then began to show general increasing irritability, impatience, and spoke a good deal more than was necessary. One week before admission he complained of pain in his extremities. He then became restless, confused, misidentified people and imagined that he was at his work ordering his subordinates to perform certain duties, etc. On admission the patient showed definite evidences of arteriosclerosis. His pupils were equal and reacted well; eye grounds showed definite arteriosclerotic changes; all his deep reflexes were accentuated; there were no pathological reflexes elicited; there was a soft, blowing systolic murmur at the apex; there was a tremor of the tongue and hands; tongue was heavily coated; red in spots and dry. His blood pressure was 130/65; his urine showed a specific gravity of 1012, a trace of albumen, and an occasional hyaline cast. His blood chemistry showed N. P. N. 34.5 per 100 c. c. of blood; creatinin 1.5 mg. per 100 c. c. of blood; and carbon dioxide 60 . . . blood Wassermann negative; blood count white blood cells 6,500—82 polymorphonuclears. Mentally he was confused, restless, spoke in an incoherent, rambling manner, and had a definite occupation delirium; throughout he showed marked fear reaction; he would often jump from the bed, look about the room saying that he had just heard people were following him or that they were threatening him. He had frequent lucid intervals especially in the middle of the day, but he was very much worse in the morning and evening. He was sleepless most of the time. At the end of three weeks he gradually improved. His blood pressure rose to 160/85; he would sleep the greater part of the night and would take his nourishment. His tongue assumed a more normal appearance. He gradually cleared mentally, but he had only partial insight. It was possible, however, to discharge him on June 13, 1922,

CASE III.—Female, white, aged fifty-six, United States, widow. Admitted June 6, 1922. A relative of this patient, who happened to be her physician, stated that he had been treating her for the past four years for general arteriosclerosis and hypertension; that her blood pressure would frequently rise to 220 systolic and her diastolic never went below 100. For two weeks preceding her admission she had had a general rhinitis and pharyngitis and had had a temperature of 101° to 102°. For about three days preceding her admission she had been somewhat confused; had complained to him that the board of health was going to dispossess her and that she was going to be killed. She had refused to go to bed as she feared that harm might be done to her. On admission the patient showed a well developed but poorly nourished physical condition. Her pupils were equal but irregular, in outline, and reacted sluggishly both to light and to accommodation. Eye grounds showed definite arteriosclerotic changes. The speech was somewhat indistinct. The tongue was red, partly coated and dry. The breath was foul. All deep reflexes were accentuated. There were no pathological reflexes. There were tremors of the tongue and hands. Her blood pressure was 135/80. The heart showed distant sounds with a systolic murmur at the apex. Her urine showed a specific gravity of 1015, traces of albumen and several hyaline casts. Blood Wassermann was negative. White blood cells 8,000 and polymorphonuclears 85. Mentally the patient was quiet but definitely suspicious. Never complained of any physical weakness or any physical condition; stated that she was feeling very well but that there was a plot to harm her; when a door bell would ring she would jump from bed and would say "there they come for me now; please don't let them dispossess me." She insisted that the board of health would dispossess her and that she would be killed during the night. She misidentified the patients about her and stated that they were agents of the board of health. She had lucid intervals especially during the middle of the day but she was quite fearful and confused in the early morning, and apprehensive during the night. After two weeks of hospital residence her physical condition gradually improved, her blood pressure rose to 155/90 and her mental condition also gradually improved. She was still suspicious and somewhat apprehensive. At the request of her relatives and physician she was discharged to their custody July 18, 1922, having partially recovered from her attack.

In conclusion, it is quite obvious that we are dealing with patients who have had cerebral and general arteriosclerosis. These patients have all had a mild infection to which they reacted poorly. Physically they showed a generally undernourished condition, poor heart action, accentuated deep reflexes, practically no leucocytosis, low blood pressure, and albumen and casts in the urine. The Wassermann was negative.

Mentally these patients showed marked fear reaction, confusion and disorientation; they misidentified those about them, had difficulty in perception and in association; admitted hallucinatory experiences and expressed some nonsystematized delusional trends. With rest in bed, forced fluid intake and care of their gastrointestinal tracts, their general condition and mental state improved, and it was possible to discharge them at the end of two to three weeks of hospital residence and after an illness of approximately one to three months' duration.

Report of a Case of Chorea

By R. SHEEHAN, M.D.,
New York.

This case is reported because of the occurrence of symptoms immediately following an injury and the cessation of pain with the beginning of the choreic movements.

HISTORY.

Case.—A boy, white; aged nineteen; born in the United States, occupation, mechanic's helper. He complained of jerky movements of the left hand, arm, shoulder and head which stopped during sleep. He stated that he has been nervous the past three years, that he has had family difficulties, particularly disagreements with his married brother over financial matters, and that he was irritable and had a violent temper. Last year he had attacks of pain and cramps, with difficulty in moving his legs which he described as rheumatism. He attributed these to the fact that he worked in an icecream factory where he was in a refrigerator for hours at a time. He had also stuttered for a number of years.

He further stated that on April 28, 1923, while working under a motor car he was using a wrench to tighten up a nut when it slipped and allowed his left forearm to strike against the frame of the car. He kept on working until the next day. That night he had pain in the arm and could not sleep. He went to a hospital where it was believed that he had a fracture of the wrist, but this was not substantiated by x ray examination, which was negative. He was given massage and baking of the arm. About May 5, 1923, his left arm started to jerk and has continued to do so, gradually getting worse.

Physical examination.—He was five feet five inches high and weighed 132 pounds. He was well built and of good musculature, chest measured 33 inches. The respiratory excursion was three and one-half inches. These was nothing abnormal regarding the heart, lungs or abdomen. The pulse was regular and of good quality, rate 76 sitting. The blood pressure was 120/85. There were no abnormalities of the joints, extremities or vertebræ. If he had an injury of the left wrist, it was not evident at examination.

Neurological examination.—There was no disturbance of gait or station. There was no subjective dizziness. There were spontaneous movements of the left arm, hand and shoulder which were quick, coarse and wide. There were also jerky movements of the head and spasmodic twitching of the mouth and eyeballs. The movements of the hand and arm interfered with coordination so that he had difficulty in making purposeful movements. These diminished with rest and relaxation. The movements were asynergic in character and entailed inability to make well adapted movements. In picking up objects, the hand was overwidely opened and in the coordination tests there was a well marked tendency to overshoot the mark. The superficial and deep reflexes were present and normal, except that there was a moderate left Babinski and Chaddock and the left plantar reflex was increased. There was no clonus. The grip of the left hand was reduced, being fifteen pounds, as compared with eighty pounds in the right. There was no alteration of sensation. There were no paralysis or neuritides.

The pupils were equal and regular and reacted normally to light and accommodation. The sympathetic and consensual reflexes were normal. There was no strabismus, diplopia or ptosis. There was no nystagmus but coarse, spasmodic twitchings of the eyeballs. There was no alteration of the color of visual fields. There was no impairment of the special senses, except speech which was stuttering and frequently gasping in character. This was not intrinsic, but due to the spasmodic movements.

He had a normal degree of insight and judgment. There was no defect of memory or intelligence.

THE INDICATIONS AND CONTRAINDICATIONS OF SPINAL ANESTHESIA

Although many surgeons, especially Chaput and Jannesco and his collaborators, have desired to make spinal anesthesia a general procedure applicable to every kind of operation on any region of the body and to take the place of general narcosis with ether or chloroform, it is probable that the majority of the surgical profession at present regard it as either a method of exception, or else as a method applicable in certain cases, but not in all. This is unquestionably the most rational view. Spinal anesthesia, whether stovain or some other similar drug is employed, has its indications and it is evident that the site of the operation is its principal indication. In spite of the enthusiasm and extension given to this procedure of anesthesia, particularly in Roumania, by Jannesco's technic, it is nevertheless true that it is above all indicated in operations on the lower limbs, anoperineal region, pelvic organs and gynecological operations in particular.

Many surgeons maintain that it is to be used only in operations involving structures below the umbilicus, but experience shows that when Jannesco's technic is employed with exactitude and manipulated with skill and prudence, the indications can be extended to all cases in which a sufficient anesthesia can be obtained by an injection given low down, that is to say in the dorsolumbar region, consequently in the majority of abdominal operations.

In those cases where spinal puncture must be made in the dorsal region in order to obtain the necessary anesthesia, that is to say for operations on the thorax and upper limb, a certain reserve is in order. It cannot be denied that many surgeons and Jannesco in particular, have obtained perfect anesthesias without accidents by high puncture, but generally speaking the anesthesia obtained in these conditions is very often imperfect. The technic is more difficult and necessitates great skill on the operator's part, not so much for the puncture itself as for the position to be given to the patient, as well as the dose of the anesthetic employed. Finally, spinal anesthesia would seem to have very exceptional indications in operations on the skull, face and neck as its use in these conditions entails real danger.

Besides the question of the site of the operation, spinal anesthesia has other indications. It possesses unquestionable advantage in army surgery or in country surgery, by doing away with an extra assistant often difficult to find. It also has advantages of another order. The patient, although insensible to pain, is conscious during the operation and in cases where his consent may be necessary for extending an interference, that is to say, removing some important organ not thought necessary before the operation, this is of utmost importance to the surgeon.

Lastly, in a general way it can be said that lumbar anesthesia is indicated precisely when there are contraindications for general narcosis from the presence of organic cardiac lesions, a renal or pulmonary process or a profound organic decline. Jannesco maintains that there are no contraindications for spinal anesthesia but in spite of his high authority in the matter, we believe that operations on the head and neck should be regarded as distinctly contraindicating this form of anesthesia, unless any other procedure of narcosis is impossible, a condition unlikely to be met with in practice. Jannesco believes that age has no bearing on the indications for the use of lumbar anesthesia and yet some competent observers maintain that it is more indicated in elderly subjects than in young because of the thickness of the scaglial which prevents diffusion of the anesthetic solution. Another contraindication is chronic visceral suppurative processes, arteriosclerosis and affections of the central nervous system, as well as renal or hepatic insufficiency when these are detected, as they should be, before operation is undertaken.

MENTAL CLINICS FOR CHILDREN

One of the notable steps taken by preventive medicine in the last few years has been the establishment of many outpatient clinics of various kinds, especially those for the care and treatment of patients suffering from nervous and mental disorders. These are of two main types—those for adults, conducted by various institutions; and those for mentally defective and unstable children. In New York State, the first type is under the supervision of the State Hospital Commission, and the second under the direction of the State Commission for Mental Defectives. In some of the largest cities a number of these clinics are connected with hospitals, private individuals, or welfare organizations.

Dr. Sanger Brown, 2nd, chairman of the State Commission for Mental Defectives, made an address on the subject of these clinics, especially those for children, at a recent conference at the Utica Hospital, which has been reprinted in the *State Hospital Quarterly* for February.

In these clinics for children, various organizations are interested—welfare organizations, the children's courts, and particularly the Department of Education, which employs a psychologist and a psychiatrist to examine school children showing evidences of mental defect or instability, and a director to oversee the formation of ungraded classes throughout the State. It carries out recommendations in the schools as to the kind of education for individual children, and as to the formation of ungraded classes in the district, but does not attempt examinations on a broad scale. Children's clinics are now being operated by the State Commission for Mental Defectives in twenty-two towns, and nine other places have asked for them. Some of these clinics are held every week, some every two weeks, some once a month, and some only occasionally.

A clinic originates somewhat as follows. A town or city sends in a request for provision and supervision for the mentally defective and delinquent children of the vicinity. Sometimes it is desired that an ungraded class be established in a school. The request may come from the children's court, from local physicians, or from social workers who need help with difficult children. The psychiatrist or one of the commission's field workers then makes a survey of the situation in the place from which the request comes, gets in touch with local physicians, judges, school officers, welfare organizations, etc., and, if it seems advisable, makes arrangements for establishing the clinic. The State Charities Aid Association attends to the publicity work by notices in local papers, announcement of clinic days, and the giving of other necessary information. A building is obtained, and the difficult work of furnishing an adequate staff undertaken. The social work and mental testing are done by the field agents of the commission, of which there are now five, one in the western part of the State, one in the northern, one in the central part, and two in New York City. The physicians are secured in various ways. The commission's psychiatrist attends some of the clinics, one or two are reached by local physicians in the community, a few come from the State hospitals, and some are furnished by the State schools for mental defectives.

The children are examined physically and mentally, and a social survey and school investigation are obtained. A diagnosis is made as far as is possible at the clinic, and the field workers attempt to follow up the case and to carry out the recommendations. About 2,000 cases have been examined at the clinics in the past two years. So far it has been the policy to emphasize the close association of the clinics with the schools. When a clinic is to be established, the psychiatrist with the department of education notifies the local principal, a procedure which tends to enlist the assistance of the teachers in carrying out the recommendations, and to encourage them to send cases to the clinic for observation. The commission, which wishes to keep a register of mental defectives in the State, and the department of education, which wishes to list all mental defectives in the schools, are furnished with clinic records, which cannot of course be complete, but which act at least as case summaries.

In these clinics problems in the whole field of child psychology are met with, as well as many types of mental defect and psychoneurotic personality. Physical defects as factors in mental retardation are found, and various forms of mental disorder resulting from physical illnesses. All kinds of delinquency and conduct disorders are dealt with. Results of treatment, however, if the recommendations can be carried out, are most gratifying.

Dr. Brown closes his paper with a plea that the State will see its way to supplying more field workers and medical officers, as the present number is far from sufficient. He believes that the most economical way to conduct the clinics will be to combine those for adults and children, at least as to place, time, and staff. When these clinics become firmly established as a State activity, their value as aids in the mental hygiene program will be doubled.

THE VARIATIONS OF ENTROPY IN CERTAIN MENTAL PROCESSES

Thermodynamics are a part of experimental physics which study the transformation of mechanical work into heat. The first condition is that there shall be equivalence between the heat produced and the work expended. This is the Joule-Mayer principle. The second condition is that it is easier to transform mechanical work into heat, than heat into work. This is the Carnot-Clausius principle.

Energetics (Rankine) is the study of physical phenomena by means of results obtained by generalizing the principles of thermodynamics, which then respectively become: 1, the principle of preservation of energy—the forms of energy interchange without modifying the quantity of total energy; 2, the principle of degradation or dissipation of energy, or principle of the increase of entropy.

Heat is the most stable of all forms of energy. The latter has a tendency to become transformed into heat which also appears as a kind of product of excretion of mutual metabolism of the other varieties of energy. As a consequence, any possible phenomenon is accompanied by an increase of entropy (irreversible) and no phenomena are known which occur without a variation of entropy (reversible). Briefly, in the universe the quantity of energy remains constant and the quantity of entropy cannot decrease.

As a conclusion it may be said that since preservation of energy and increase of entropy are two conditions of physical phenomena as time and space are two conditions of psychical phenomena, one may consider space and energy, and time and entropy, as two notions equivalent to one condition.

To demonstrate the logic of this conclusion, it must be proved that the principles of energetics apply to mental phenomena. These proofs are of two kinds, indirect and direct. As indirect proof, phylogeny offers a marked analogy of constitution between the muscular and nervous system, while the physiology of the muscular fibre is almost identical to that of the neuron. The same mechanical conception explains the functions of both organs; both are electrocapillary systems. Finally, in both, heat is a product of excretion; or, each one degrades energy and increases entropy during its functioning.

The direct proofs should show in the first place that not only the neuron transforms energy—the study of the time of reaction, but also that it degrades it, as is demonstrated by the data obtained by means of the Weber-Fechner law. This socalled law simply signifies that any preliminary excitation of the nervous system has increased its entropy—stability—hence rendering it less sensitive to a second excitation.

Applying these conclusions to diseased nervous systems, such as are represented by the mental states in hereditary degenerates, it may be said that normally the entropy constantly tends to undergo an average increase in the individual and his descendants (irreversibility). When this increase becomes almost nil (reversibility), the stability of the nervous system is practically nil, hence the degenerate is characterized by a dissolution of the laws of heredity and by an absence of mental stability.

This state of irreversibility of mental phenomena may affect an individual by changing (a) the personal psychical acquisitions from disturbance of the memory, of sensations (hallucinations) or associations (mental confusion), (b) the attitude of acquiring ideas and sensations (delicious interpretations), (c) the possibility of reversibility of mental phenomena causes affective disturbances to appear, either systematized — obsessions, or non-systematized — mania, melancholia, etc.

When, on the contrary, instead of being nil or average, the increase of entropy is very great, we then have those mental states susceptible of acquiring an extreme stability which characterizes the man of genius.

The difficulty to distinguish genius from degeneration is only apparent and arises from the fact that in both instances there is a dissolution of heredity, whose preservation is the apanage of banality.

Such are the conclusions derived from purely experimental notions of energy and entropy in place of metaphysical notions borrowed either from pure psychology or from automechanical theories.

NURSES FOR MENTAL DEFECTIVES

It has been fully recognized for some time that workers with the feebleminded require special training and preparation for their work. It is a self-evident fact that the nurse engaged in social work, in industrial or school nursing, or in public health work comes in contact almost daily with cases of subnormal or feebleminded children. The executive of the nursing divisions of institutions for mental defectives must have a very special knowledge of the causes, signs and symptoms, care and treatment, and education of such atypical cases. After the institution or the school has done all possible for such types of defectives, the most careful follow up and supervisory work is necessary so that these individuals may not be left to be a menace to the community.

According to a recent article on this subject by Mrs. Ann How, Superintendent of Nurses at the Children's Hospital on Randall's Island, the defective child will always be defective and the work of the special classes and other agencies can do no more than fit him for his place of limited range in the community. Yet it is a recognized fact that many of the higher grade defective children can be trained to be industrially efficient and selfsupporting, and can be made useful citizens of the community, provided proper supervision is supplied. Groups in various institutions have been trained through occupational therapy to do many kinds of handiwork, the returns from which enable them to contribute considerably to their own support. Other groups have been trained for efficient house service in the institutions caring for them, and some of these individuals are on the payroll and have started bank accounts of their own. To accomplish this, and to provide the proper supervisory care for its attainment, the head of the institution must have beyond all else vision and, contributory to this, the proper preparation and training as a background.

To prepare nurses for work which brings them in contact with mental defectives as outlined above, and to train executives for positions in institutions caring for the feebleminded, the New York City Children's Hospital and Schools at Randall's Island will offer a course of training to graduates from nursing schools of recognized standing. The initial classes will form October 1, 1923, and the course will be of three months' duration. Lectures will be given not only by heads of departments and instructors in the Randall's Island Schools, but by wellknown authorities on psychiatry and social work with mental defectives. The course will include practical work in the schools of the institution, in the psychological laboratory, and in the wards of the hospital. Certificates will be granted to nurses successfully completing the course.

Such a course will fill a real need in the community, and a wide response from professional nurses who wish to avail themselves of this opportunity for service of a most vital nature is anticipated.

SURGERY OF THE PERIPHERAL NERVES

At the Sixth Congress of the International Society of Surgery held in London, a short time ago, one morning session was given over to the reading of papers and discussion on the surgery of peripheral nerves. It need hardly be pointed out that the experiences of the war greatly enlarged the knowledge of the subject, and although the conditions of war cannot be applied by any means exactly to those of peace, yet it stands to reason that many, perhaps most, of the lessons learned in this branch of surgery during war will be valuable surgical acquirements in the time of peace. Some surgeons are inclined to lay too great stress on the difference of conditions. In industrial warfare as carried on under modern conditions nerve injuries are quite frequent.

Among the papers read at the Congress was one by the great French surgeon Professor A. Gosset, of Paris. He holds that the wounds of the nerves which should be operated on are (a) all the cases of progressive compression that grow worse and lead to the syndrome of serious irritation or interruption, (b) all the cases of complete interruption, clinically observed by competent neurologists after repeated examinations, and which show no sign of regeneration or show useless signs of regeneration like zones of limited stationary paresthesies and exhibit no sign of improvement, (c) for causalgia and serious neuritis, recourse should be had to an operation.

Professor Gosset indicates when to operate as follows: (a) The lessons of war surgery, which tended more and more to favor prompt operations, have shown us that we certainly have the right, even the duty, to examine during the preliminary surgical cleaning of the wound, the state of the important vessels and nerves. This is still more necessary, if, from the first day, there are signs of paralysis of a large nervous peripheric trunk. Any severed nerve should be, at once, stitched up so as to permit of rapid regeneration and thus, moreover, avoiding the deviation or the formation of sclerous tissue; in the case of a bruised nervous trunk, its preservation and constant observation seem to be preferable. (b) If some time has elapsed before the wounded subject has received medical attention, the diagnosticated lesion should be operated upon as quickly as possible, but nevertheless it is necessary to wait until the suppuration, the osteitis, and the inflammatory symptoms have disappeared for some weeks.

This is what Dr. Gosset advises should be done: (a) Simple liberation, with replacement between healthy muscles, is applicable to the syndromes of compression and of irritation. The enucleation of small intrafasicular fibroms should be practised only when it is without danger for the healthy nervous fascicles; the intranervous extraneous bodies should always be taken out. (b) Should the interruptions be examined several times, without any improvement being remarked, resection of the fibrous callus and neurilematic suture uniting two permeable ends, without traction at the level of the suture threads, should be practised. If the suture is impossible, a graft, or the dividing into two of the lower end, disguised graft should be practised. Useful results will be obtained only if the wounded subject has been kept without ankylosis, without muscular retraction, during the time preceding the surgical treatment. This treatment should not be given over too early, because experience has shown that it depends on the nerves themselves affected, on the suture or the graft, whether the period of regeneration may last from eighteen months to several years.

Dr. Gosset emphasizes that two cases should be distinctly distinguished. In war surgery, as well as in civil surgery, immediate suture of the nerves should normally be completely successful. Delayed surgical treatment may give good functional results in forty to fifty per cent. of the cases, according to the state of the nerves, when it has been performed from one month to two years after the injury was received. Even after that time it should be tried; it may be successful but Dr. Gosset agrees with most medical authorities that there is less chance of success. Nevertheless, the surgical treatment of the big nervous trunks is by no means illusory if it is carefully and systematically practised by specialists who are equipped for that purpose, and when the patient can be kept under prolonged observation. In these circumstances satisfactory results are possible.

Dr. Charles H. Frazier, of Philadelphia, discussed the results of three thousand gunshot wounds of the peripheral nerves treated in the reconstruction hospitals under the control of the Surgeon General's office, U. S. A. As regards the quality of recovery from resection and suture, according to Dr. Frazier's experience it is rarely perfect and the question of the bearing of the intraneural plexuses on this elicited. It is difficult to account for the high percentage of failures in certain nerves, external popiteal for instance. Neurolysis had failed in twenty-six per cent. of cases. Finally he thought that results had been sufficiently good to warrant the reexploration and suture if possible in cases of complete lesions of the median, ulnar, musculospiral and sciatic.

Mr. H. Platt, of Manchester, and Mr. W. R. Bristow, of London, contributed a joint paper in which they stated without reservation that the results of nerve suture had fallen short of expectations as was shown by an analysis of the true end results published for the first time by Professor J. B. Stopford. Also it was stated that many claims to success from grafting had been examined by the Medical Research Council and all had failed to convince. On the whole the impression left by the papers read and by the discussion which followed was that nerve surgery was not greatly successful, at least, war experience fostered such an opinion. However, it should be borne in mind that conditions in civil life are more favorable than during war, sepsis should be less frequent, and therefore better results should be expected. At any rate, the experience in this delicate and difficult branch of surgery gained in the war has taught a good deal which cannot but be valuable in civil conditions.

PAIN IN THE MIND

In a recent lecture on vaccination, Sir Almroth Wright declared that "emotional tension is intolerant of any intellectual *impasse*." He was describing in outline the steps by which modern medicine has progressed towards a clearer knowledge of disease and of the mechanism of the body's protection against disease.

Hypotheses are invariably tentative; of the best of them it may be said that, in a sense, they are made to be destroyed. Thus it was, to quote Sir Almroth again, the pain in the mind, which is felt when "one is appealed to and is powerless," which led Pasteur to revise his first theory of vaccination and so to achieve his great triumph over hydrophobia.

Last June, at St. Mary's Hospital, London, Professor Dreyer, of Oxford, offered still another extension of knowledge which is the outcome of revised opinions and changed ideas. His new treatment of tuberculosis, whether ultimately it stands or falls, is the last link in the chain extending back to Jenner. The chain is continuous, but its links if the metaphor may be extended, are not of the same shape nor even of the same metal.

Sir Almroth Wright has recently outlined his own revised opinions on the subject of vaccination against disease. These differ in many important respects from the views this pioneer held when he set himself to perfect the method of preventive inoculation against typhoid fever, which stood the world in so great stead during the years of the war. He no longer believes that our bodies elaborate a special and specific antidote against each germ that attacks them. Rather he takes the view that there is stored up in the while cells of the blood a common stock of antidote which may be released very swiftly and which is capable of inflicting death on most of our microbic foes. These are revolutionary opinions and it would be idle to pretend that at present they meet with general acceptance. Their importance, however, cannot be denied. Nor is it likely that the "pain in the mind" which gave them birth will suffer them to remain without the sustenance of continuous, experimental, proof. Vaccination is now fighting for first place among the weapons of cure and, thanks to such men as Wright and Dreyer, as well as many others possessed of the same temper of mind, it has literally forced itself on the world. Failure in more than one direction has already been changed into conspicuous success; no failure has been accepted as inevitable or irremediable: It may be that this urgent spirit is about to win its greatest triumph and that a new vista of hope is opening before us. In any case the future is pregnant with possibilities, inasmuch as many minds in the scientific world at this very moment are held in that "emotional tension" from which all progress and discovery emanates.

MENTAL CAUSES OF ACCIDENTS

A recent issue of the *National Safety News* contains an interesting article, with charts, by W. R. Woodbury, on mental factors in the prevention of industrial accidents and casualties. The chief mental causes of this type of accident emphasized are: 1, ignorance of the English language; 2, inexperience, including distractions, unfamiliar surroundings, and over anxiety and zeal on the part of beginners; 3, a curious mental limitation observable in some workers which seems to make it impossible for them to avoid accidents, and which they can rarely be trained out of; 4, sense defects; 5, faulty mental attitudes, such as fatalism, antagonism toward medical treatment, and timidity; 6, socalled mental sets—the chronic kicker, the grouch and the rabid radical are the victims of mental sets; 7, the tendency to extreme excitability, which may, however, be trained out of some workers; 8, unconscious errors, such, for instance, as those made when a worker is changed from a machine to which he has become accustomed to a new one of a slightly different type; 9, faulty habits, such as habitual carelessness and undue haste; 10, inattention and lack of interest in the work; 11, preoccupation, including worry, strife, mental disorder or depression; 12, sickness; 13, faulty plant conditions, such as dirt, poor lighting and ventilation, and impure drinking water; 14, fatigue, not necessarily the result of overwork, but of difficult living conditions, undernourishment, lack of sleep, worry or emotional stress.

RELIEF FOR EUROPEAN PHYSICIANS

New York, *September 24, 1923.*

To the Editor:

I wish to make this appeal to the American physician through the New York Medical Journal. You know of course that with the depreciation of currency the countries of Central and Eastern Europe have been pauperized. The people are no longer able to employ the services of physicians, and cannot pay for indispensable medical treatment. As a consequence, the medical profession is reduced to a state of starvation, and public health is being undermined. Over ninety per cent. of the people are being cared for by the Krankenkassen (state insurance) with the result that the doctor is paid less than two cents a call, if anything. Many doctors have been compelled to take up additional work in the mines, on street cars, etc., in order to earn enough to keep body and soul together; many, in desperation, have committed suicide.

Steps for the relief of this situation are imperative. This is the time for Americans to lend a helping hand to the starving physicians. A committee has been formed for this purpose and has organized the Association for the Relief of Needy Physicians of Central and Eastern Europe (Austria, Germany, Freestate of Danzig, Lithuania, Poland and Russia). The object of this society is to collect funds in the United States through subcommittees established in all the large cities and to use this money to support the medical profession abroad until they are again in a position to take care of themselves. The individual contributor is requested to designate the country to which his contribution shall be applied. Undesignated sums are to be divided by the Central Committee according to its best judgment.

Checks may be mailed to the treasurer, Mr. Henry C. Steneck, 265 Central Park West, New York City. We have no administrative expenses; all printing, stationery, clerical help, etc., is furnished free by the Steneck Trust Company, so that every cent collected is used for relief.

Very truly yours,
Max Einhorn, M. D., President.
20 East Sixty-third Street.

◆

News Items.

Neurologic Clinics Open.—The Neurological Institute, at 151 East Sixty-seventh Street, announces that they will open a night treatment clinic for men and another for women on Tuesday and Friday evenings at 7 p. m. The men's clinic will be open on Monday and Thursday evenings.

Dr. Elizabeth M. Gardiner Joins State Health Forces.—State Commissioner of Health Nicoll announces the appointment of Dr. Elizabeth M. Gardiner as associate director of the division of maternity, infancy, and child hygiene of his department. Dr. Gardiner has resigned the directorship of the child welfare division of the Rhode Island State Department of Health to join the health force.

Nansen Coming to Talk on League.—Dr. Fridtjof Nansen will visit the United States and Canada this winter, according to the League of Nations Society in Canada, under whose auspices he will make several addresses. Dr. Nansen is due to arrive in New York November 2nd.

Leidy Centenary.—Dr. William Darrach, dean of the medical faculty of Columbia University, will represent Columbia University at the celebration of the centenary of the birth of Joseph Leidy, the American naturalist. The meeting will be held in the Academy of Natural Sciences at Philadelphia on December 6th.

Health Day to Be Observed.—Announcement has been made that November 13th has been set aside as Health Day in the schools of New York City. On that day all regular work will be put aside and the time given to matters pertaining to health. Every teacher will examine her pupils, and send those she thinks need attention to the department of hygiene.

Dr. Carroll to Study Abroad.—Highland Hospital announces that its medical director, Dr. Robert S. Carroll, has been granted one year leave of absence for study and travel in Europe and the Orient. The directorship of the hospital will be carried on by Dr. Everett S. Barr, until recently the medical head of Philadelphia Hospital for Mental Diseases.

Dr. Wenyon to Succeed Balfour.—Dr. Andrew Balfour, C. B., C. M. G., F. R. C. P. E., for the past ten years chief director of the Wellcome Bureau of Scientific Research, London, resigns that position on October 31, 1923. He will be succeeded by Dr. C. M. Wenyon, C. M. G., C. B. E., M. B., B. Sc., who for the past nine years has been director of research in the tropics of the Wellcome Bureau of Scientific Research.

Medical Society Announcement.—Under the auspices of the Medical Society of the County of Kings the second fall term of talks entitled The Practical Lecture Series will open on Friday afternoon at 5 o'clock, October 5th, at the Library Building, 1313 Bedford Avenue. There will be ten lectures, each one of a practical nature and designed especially for the general practitioner. To date thirty lectures, of one hour's duration, have been given. These talks are part of a plan of free postgraduate medical education which is beginning its second term under the direction of joint committees of the Long Island College Hospital and the Medical Society of the County of Kings. Those interested in this matter may write to the dean of the Long Island College Hospital, Henry Street, Brooklyn, N. Y.

New York Postgraduate Medical School Announcement.—A course of lectures is announced by the Postgraduate Medical School and Hospital to be given on Friday afternoons at five o'clock during the coming season. These lectures will be free, and all members of the medical profession in New York City and vicinity are invited to attend. The following lectures are scheduled for next month: October 5th, The Treatment of Nephritis, by Dr. Arthur F. Chace; October 12th, A Diagnostic Clinic, by Dr. John F. Erdmann; October 19th, The Pathology and Prognosis of Eye Changes in Diabetes, by Dr. Max Cohen; October 26th, Uterine Hemorrhage—Its Significance and Treatment, by Dr. Henry Dawson Furniss.

Book Reviews

STAMMERING

No Need to Stammer; or, Reeducation of Speech for Stammering and Cleft Palate. By H. St. John Rumsey, M. A., with an introduction and chapter on Respiration by J. F. Halls Dally, M. A., M. D., B. C. New York: Dodd, Mead & Co., 1923.

The reading and study of this practical little book of only seventy-five pages should be of real help to persons suffering from the most common speech defects—stammering, socalled stuttering, and the difficulties arising from cleft palate. The book includes a nontechnical discussion of causes, a simple description of the vocal and respiratory mechanisms with their relation to proper methods of speaking, and exercises and directions for breaking the habit. The author believes that most stammering arises from careless habits or bad training in early life, but there are of course also cases that have an emotional basis, such as fright, shock, or sometimes an acute illness, as the causative factors. He emphasizes the great handicap of the stammerer and mentions one of his patients who declared that the shell fire in the trenches of France had never been able to frighten him so much as the opening of the door of his business office when he was alone, meaning that he might have to answer a question. As to the possibility of cure for the stammerer, the answer in every case the author says is, "Yes, if one has the patience and strength of character to follow sound advice and break down this distressing habit. The stammerer must have a real desire to overcome his trouble—he must have patience and determination in no small degree. Without these the best advice in the world will be wasted. On the other hand, if the patient is keen, willing and determined, the cure will be absolutely certain."

LAUGHTER

The Psychology of Laughter and Comedy. By J. Y. T. GRIEG, M.A. New York: Dodd, Mead and Company, 1923. Pp. 304.

Grieg has written a book excellent in form and of a subject matter old and yet new in his manner of presentation. His style is engaging as the reflection of a writer broad enough to challenge his reader to agree with him or to disagree, to laugh at his theories or to laugh with him, that is to find in them at least something which gives psychological phenomena another turn over in the interests of further enlightenment. Grieg keeps his own psychological position, whether in regard to laughter and comedy or other phenomena, free from dogmatic committal but is not afraid to state his beliefs and his train of psychological inquiry in sufficiently positive terms.

His viewpoint is genetic enough to lead him to investigate his subject first of all among children or rather infants. Here, a fairly close follower of Freud, he finds that the smile and then laughter appear as an accompaniment of the love instinct. The latter, "uncertain and illcoordinated" in its behavior, is subject to interruption through obstacles appearing in its way. Then the as sudden overcoming of this interruption leads to laughter. Hate lies close enough to love to give opportunity for laughter and comedy to find the pathway of hate as well as of love. Grieg finds it possible to trace all more complicated forms of laughter producing phenomena as but elaborations of this simple formula.

Grieg acknowledges his special indebtedness to Sully and Freud. He has examined the theories of both as well as of other writers upon the subject. He appends a summary of such writers down through the ages of literature. He also adds an extensive bibliography.

PSYCHOLOGY OF MIRACLES

Miracles and the New Psychology. A Study in the Healing Miracles of the New Testament. By E. R. MICKLEM, M.A., B.Litt. (Oxon). Oxford University Press, London: Humphrey Milford, 1922.

The author of this small volume need have made no excuse for adding to the many publications upon the socalled new psychology. He has carried the principles of it, in its various methods of therapeutic application, into a field of much psychological interest. He touches briefly upon theological and historical questions pertaining to the record of healing miracles of the New Testament but merely to dispose of these in a way to pursue the simple road of psychological explanation. In this task he feels his way questioningly rather than dogmatically. He himself lays special emphasis at the end upon faith in God without pursuing in regard to this the psychological factor of transference at which he has elsewhere hinted. But on the whole his work is an unprejudiced examination of possibilities of interpretation. It is a fair review of the various psychotherapeutic methods rooted in the new psychology. It also presents interesting material from the modern world, enlightened and superstitious, which he brings into comparison with the biblical situations. The book is presented in scholarly form and suggestively opens an interesting field for further study.

PSYCHOLOGY AND TEACHING

The New Psychology and the Teacher. By H. CRICHTON MILLER, M.A., M.D. New York: Thomas Seltzer, 1922. Pp. 225.

This is a book which gives many valuable suggestions of a sort to stimulate teachers and parents to a sense of their responsibilities to the needs of children as modern dynamic psychology realizes those needs. It sets forth in part the difficulties which are not ordinarily recognized as hindrances in the way of the child's development and points out the ways in which the psychology of the unconscious brings understanding and help in the face of the child's problems. There is, however, an incompleteness in all this, an incompleteness which carries the danger of imperfect direction because of the failure to penetrate sufficiently into the fundamental facts of the unconscious and to follow then their significance in the mental life. This failure is indeed a deliberate choice of the less adequate means of really analyzing the psychic life upheld by the author in his strong championship of Jung's conception of the unconscious. It reveals the idealism to which this tends at the expense of recognition of the basic facts upon which alone idealism could find a sure foundation. The author makes the familiar criticism that Freud's psychoanalysis has no such progressive goal and is unmindful of the individual's relation to the herd. All of which criticism reveals lack of comprehension of Freud's psychoanalysis and an unwillingness, conscious or otherwise, to search to the utmost among the things of the unconscious.

HYPNOTISM

Hypnotism and Suggestion. By Louis Satow. Translated by Bernard Miall. New York: Dodd, Mead and Company, 1923, pp. vii, 290.

This book should serve as a purifier of thought among readers of English as it is designed to be in its original tongue. The author has reviewed the history of hypnosis and suggestibility as these have been utilized popularly, religiously, pseudoscientifically and scientifically. He shows how the underlying principles upon which all such activity is built are reducible to scientifically definable terms. He inveighs courageously against the bondage to superstition and unthinking obedience to authority which characterizes man everywhere and at every age. He cries out against it as he points to its effect in producing wars and maintaining a belief in war. He shows the close psychological relation of this latter manifestation of "mass psychology" with other movements which have swept man into various forms of fanatic behavior. He shows also how the same psychic background out of which these things may arise is that which can be utilized for a sane and helpful therapy. In thus discussing the ground and the nature of hypnosis and suggestive treatment he has failed to penetrate into the determinative factors within the unconscious personality which make hypnosis possible, which are the very basis, indeed the very essence, of hypnosis and suggestion. He points in that direction with a forceful aiming at the truth that propels his reader into further questioning for himself. But he has not made sufficiently clear how the phenomena he discusses are rooted in the personality of the subject not injected from without. Why has Satow so consistently avoided all mention of psychoanalysis and its penetration of the unconscious? Why also when he states his preference for the term unconscious does he persist in using the term subconscious? He knocks at the door of the unconscious but goes away without investigating what is within. His translator, who has well rendered this valuable book, goes further with at least a psychoanalytical glossary appended to this English edition.

CHRISTIAN SCIENCE

Christian Science and the Catholic Faith. Including a Brief Account of New Thought and Other Modern Mental Healing Movements. By A. M. Bellwald, S.M., S.T.L. New York: The Macmillan Company, 1922. Pp. xvi, 269.

This study presents an example of lucid thinking, clear exposition, and broad psychological interpretation. These qualities make of the book a valuable contribution from the author's own hand, while they also present his material in a manner that reveals the rich psychological interest in the matter presented. The writer's review of mind cures through the past and the present is approached with understanding and his revelation of the dominantly egoistic personality of the founder of Christian Science is also a valuable psychological study. This may be said also of his interpretation of the hold of Christian Science upon its many adherents and of its therapeutic efficacy, real or falsely claimed. The writer stops at final acceptance of certain doctrines of his own faith when the way might have been more fruitfully left open for further keen investigation. He also manifests too little knowledge of some forms of mental therapy to dismiss them as lightly as he has done. Did he mean that Freud was actually "defunct" or only his system? Either belief would fade before a fuller examination of facts. These are indications of the way in which the stimulating thought of the writer leaves the reader only with regret that he has not permitted it all the freedom which it might have exercised.

TWINS

The Physiology of Twinning. By Horatio Hackett Newman. The University of Chicago Press, Chicago, Illinois.

Newman has presented a study upon the physiology of twinning to furnish fuller evidence to the theory set forth by him in his former study upon its biology. He has pursued the phenomenon of twinning through lower zoölogical forms and considered it with its possibilities in human embryology. He shows clearly that polyembryony must not be confused with true twinning. The latter is strictly a dichotomy due to a change in the axial gradient of development. When retardation occurs for one reason or another, the integration of the organism is weakened. Then the tendency for parts of such an organism to develop independently is manifest in the development of new axes which form the line of growth of two individuals where there was one. If an embryonic organism is divided into two equivalent regions each of these regions shows itself totipotent for complete development. Double monsters arise when the separation does not form equivalent halves, double organs if only special organs are involved. All these phenomena are therefore explicable upon this same gradient theory of twinning. Budding and transverse fission are not forms of the same phenomenon. The author therefore suggests a workable classification of the various modes of reproduction under the main divisions of axiate and nonaxiate reproduction. His theory excludes the consideration of twinning as a reversion to an ancestral condition.

PSYCHOLOGY OF OLD AGE

Psychologie et Développement de l'Enfance à la Vieillesse. By Ch. de Montet et H. Bersot. Ernest Bircher, Berne, Société Anonyme, 1922.

There is disappointingly little in this book although it contains a collection of observed facts in the growth of intellectual activity. They are viewed and interpreted along lines still too close to the older superficial psychology. Under the title one expects today richer gleanings in the field where intellectual growth is only one manifestation of a teeming psychic activity. A few hints that the mental life is such a whole are given but the full significance of such a fact seems to have escaped the authors of the book.

BRAIN AND SPINAL CORD

Kompendium der topischen Gehirn- und Ruckenmarksdiagnostik. Von Robert Bing. Funfte, vermehrte und verbesserte Auflage. Mit 102 zum Teil mehrfarbigen Abbildungen. Berlin and Wien: Urban & Schwarzenberg, 1922. Pp. viii-242.

Bing scarcely needs an introduction to American neurologists. This, his fifth edition, marks many minor and a few major additions to his standard manual on topical localization. Much of the material in this as well as his fourth edition has been gathered from findings during the Great War.

DISEASES OF THE LUNGS

Lehrbuch der Lungenkrankheiten. Von Dr. Adolf Backmeister. Mit 107 Textabbildungen und 4 teils farbigen Tafeln, Dritte neubearbeitete Auflage, Leipzig, 1923, Verlag von Georg Thieme.

This is one of the latest publications among the numerous textbooks on diseases of the lungs which have appeared of late by English, French, and German authors. Bacmeister, the author of this *Lehrbuch* (textbook), has the distinction of being not only an adjunct professor at a university, but at the same time the medical director of one of the largest and best known German sanatoria. In this volume of 350 pages, the greatest attention is, naturally, paid to pulmonary tuberculosis. It is gratifying to see the first chapter devoted to the anatomy and physiology of the lungs, for here matters receive attention which are usually omitted in the modern textbooks, such as, the chemistry of respiration, the relative pressure and mechanism of respiration, etc. It is surprising, however, that the author should include cough in this chapter, cough being a symptom that can hardly be considered as a physiological phenomenon.

The second chapter is devoted to the examination of the normal lung in the living adult. This chapter, while not offering anything new, is nevertheless interesting and instructive because of its numerous illustrations, which not only describe Kroenig's and Goldscheider's methods of percussion but give also several röntgen pictures of the normal lung.

Chapter III is devoted to the pathological changes which may accompany pulmonary diseases. An excellent illustration of club fingers in a case of bronchiectasis is given which should be a reminder to those who believe that this phenomenon is exclusively found in pulmonary tuberculosis; that in reality it is found in all chronic pulmonary diseases such as chronic emphysema, chronic pneumonia, and neoplasms of the lungs. The habitus phthisicus, emphysematous and paralytic thoraces are also well illustrated. Then comes a description of the well known auscultatory signs in these affections. Nothing new is offered in the discussion of the various frequent pulmonary infections not due to the tubercle bacillus. The author does not even mention serotherapy in connection with the treatment of whooping cough.

Chapter IV is devoted to trachites, bronchitis, and bronchopneumonia. The author pays a good deal more attention to inhalation therapy than we are accustomed to do in this country.

Chapters V, VI, and VII are devoted to the discussion of such affection as tracheal and bronchostenosis, and various types of pneumonia, pneumoconiosis, and lung abscesses. It is regrettable that in any discussion on pneumonia written in the year 1923, the admirable work of Cole and his associates at the Rockefeller Institute on the three types of the pneumonia cocci and the specific treatment of this disease, based on the character of these different types, should receive recognition and recommendation by but a few lines of reference. As a new specific remedy, the author recommends optochim (optochinum basicum five times daily, 0, 1-0, 2 in milk).

The ninth chapter is interesting because it treats of the rarer manifestations in lung pathology, such as edema, syphilis, actinomycosis, and neoplasms.

The rest of this volume is entirely devoted to pulmonary tuberculosis. Here the author gives his personal experience, which is interesting, but again nothing really new is offered. He speaks favorably of tuberculin; but admits freely that the greatest caution is necessary in its administration, particularly in the adult. He admits that he has seen disastrous results from the use of this remedy and now gives tuberculin only in early and slowly progressing cases. In this country we have long since been convinced of the uselessness of Friedmann's treatment of serum as a prophylactic and curative measure in tuberculosis; but Bacmeister devotes nearly a page in this new work to telling us that according to his experience, Friedmann's remedy has no curative or preventive effect on the disease and its use should be abandoned. Nevertheless, we have been informed that Friedmann received a professorship.

The complications in pulmonary tuberculosis, such as pleurisy, pneumothorax, etc., are briefly but intelligently treated. The chapter on artificial pneumothorax and surgical treatment is abundantly illustrated by röntgen pictures which makes its perusal particularly instructive.

The author of this work is to be congratulated on having been able to cover so vast a subject as all the known diseases of the lung in such an admirable, concise, and yet comprehensive way, and the students able to read medical German, will find Bacmeister's work an instructive and interesting addition to their libraries, and a book to be frequently consulted.

COLLECTED PAPERS

Clinics and Collected Papers of St. Elizabeth's Hospital, Richmond, Virginia. Volume of 1922. St. Louis: C. V. Mosby Company, 1923.

This book is the first of an annual issue of clinics and collected papers of St. Elizabeth's Hospital. The contributions consist of clinics and papers by members of the staff of St. Elizabeth's Hospital. The first three articles give a description of some of the administrative features of the hospital. The avowed purpose of the book is not alone to collect and record the papers that seem to be of some value, but to give clinical case reports that are interesting and which would not justify a full paper on the subject. A large number of the contributions are from the pen of Dr. J. Shelton Horsley covering his most important papers during the past six years. Dr. Warren T. Vaughan has contributed a number of clinics and papers on subjects of interest to internists. The clinic on allergic headache is of special interest. Dr. Fred M. Hodges has a number of papers on roentgenographic subjects. The illustrations by Helen Lorraine are uniformly good.

HEMATURIA

Die klinische Bedeutung der Hämaturie. Von Professor Dr. Hans Rubritius. Wien, Leipzig und München: Rikola Verlag, 1923. Pp. 34.

This little monograph is an excellent treatise on the clinical significance and the determination of the cause of hematuria. The differential diagnosis of the various disease pictures associated with hematuria in the male and female is discussed. It is of particular interest to the general practitioner.

◆

Medicoliterary Notes.

The Book of Good Health, dedicated to the Mohammedans of North Africa by the Pasteur Institute, is the title of a little book recently issued by the Pasteur Institute of Algiers to instruct the people to whom it is dedicated in the prevention of disease. It is purely hygienic, never medical, in treatment, and puts the rules of health in simple, picturesque language, adapted to the rank and file of readers of the Koran. Other countries would do well to follow the example in publishing for the masses so sane, simple, yet scientific a compendium of the classical rules of hygiene. The book is edited by Dr. Parrot and printed in Paris by the Imprimerie Nationale.

* * *

Another foreign publication of significance is the new nursing journal entitled *L'Infirmière Française* (*The French Nurse*). Professor Calmette, founder of the dispensary in France and an enthusiastic supporter of public health nursing, is editor of the journal, and has a staff drawn from eminent French specialists. It is published by A. Poinat.

* * *

An amusing article in the *New Republic* for August 29th is on Colyumism as a national trait. The writer is Mary Ellis Opdycke, a New York critic and journalist.

* * *

Dr. Walter H. Brown, Director of Child Health Demonstration, Mansfield, Ohio, has an instructive article on the Trend of Maternal and Child Hygiene in the *American Journal of Public Health* for August. In the same number Dr. Dwight Lewis, of the Department of Health of New Haven, writes on the value of the sanitary index for the comparison of the health of different communities.

* * *

The Hobo, by Nels Anderson, recently published by the University of Chicago Press, is a study of the American tramp from a broadly human and very honest point of view. It is probably the best book on the life and problems of the various kinds of vagabonds—hobos, bindle bums, home guards, punks, wolves, dinges, shovel stiffs, and gay cats are some of their designations—since Josiah Flynt's *Tramping with Tramps* was published.

* * *

Statistics of Industrial Accidents in the United States, by Lucian W. Chaney, has recently been issued by the Bureau of Labor Statistics as Bulletin 339. The chief value of the report lies in the fact that it contains more information than has heretofore been collected on the various severity rates in the different industries and departments of industry. The severity rate is preferable to other methods of indicating hazard because its elements are more stable and uniform than others that might be chosen.

* * *

An interesting study of the subconscious is Evelyn Scott's *Escapade.* It is a brilliantly written novel, the scene of which is laid in Brazil. The author herself characterizes the book as a creative autobiography.

* * *

The Health Speaker's Handbook is the title of a valuable little pamphlet by Dr. Iago Galdston, recently issued by the New York Tuberculosis Association. It covers the subject of public speaking as a successful method of health education, giving suggestions on the use of slides, choice of material, duties of the chairman of meetings, and includes outlines of talks given before various types of audiences.

The first stationary bath tub in the United States was built in Cincinnati and installed in a home there in 1842. It was denounced by the papers as an undemocratic luxury, and, stranger still, the medical men of that day declared it to be a menace to health. —*Northwestern Health Journal.*

* * *

The *Illinois Institution Quarterly* for March contains the first annual report of the statistician of the Department of Public Welfare. It is a lengthy document, filling nearly 100 pages of the *Quarterly,* and containing many interesting tables, charts and maps.

* * *

Leprosy has been found to be quite amenable to treatment, according to a recent report by the United States Public Health Service on conditions during the last ten years at the Kalihi Hospital on Molokai Island. A considerable percentage of the lepers segregated there have been paroled; that is, released as being "not a menace to the public health," but it has been required that they report for examination at stated intervals. The whole number paroled was 242; of these 31 had relapses, but 7 were paroled again, and 10 were completely released.

* * *

The Columbus State Hospital, of Columbus, Ohio, is the oldest institution of the kind west of the Alleghenies, according to a letter written recently to the *Illinois Institution Quarterly* by its superintendent, Dr. William H. Pritchard. In 1835 the Ohio Legislature established an institution which became known as the Central Ohio Lunatic Asylum, and which received its first patients in 1838. Before that time the old Commercial Hospital in Cincinnati, founded in 1821, received mentally diseased persons from the whole State of Ohio.

* * *

According to a recent report of the New York Census Committee, this city leads both Chicago and Philadelphia in its ratio of residents under twenty years of age, and also under thirty. The statistics showing this were tabulated by Dr. Walter Laidlaw.

Practical Therapeutics

ALCOHOLIC INJECTION OF THE GASSERIAN GANGLION FOR TIC DOULOUREUX*

By George M. Dorrance, M. D.,
and
J. William Bransfield, M. D.,
Philadelphia.

The use of alcoholic injections into the various divisions ot the fifth nerve for the relief of trigeminal neuralgia is an established procedure. The relief obtained varies from seven months to all times, dependent upon the infiltration obtained..

It is the injection of the ganglion itself that we are interested in and here a wide divergence of opinion exists both as to the rationale of the method and the length of time relief is obtained. We are inclined to believe that in the hands of an experienced operator, when a successful injection into the ganglion is made, the relief is permanent.

In 1911, Taptas, of Constantinople, made the first successful subcutaneous injection of alcohol into the ganglion while attempting to inject the third division although Sicard, in 1910, injected the ganglion after exposing the foramen. In 1916 we published an article on the Technic of Injecting the Gasserian Ganglion with Alcohol (1), and since that time we have been employing this method. We are still of the opinion expressed at that time that the operation advocated by Spiller and so successfully followed by Frazier is the ideal method in the hands of experts where a major operation is desired by the patient. We have had cases referred to us where socalled open operation was absolutely refused both by the patient and the family doctor and in these cases we have injected the ganglion with perfectly satisfactory results. Our earliest case is now of seven years' standing with complete relief of all pain and complete anesthesia in the area supplied by the fifth nerve.

The objections raised to the use of alcoholic injections into the ganglion have been based on the earliest cases done when the technic was not perfected and when operators with little skill or knowledge of the principles involved were using what was believed to be a simple procedure. The same training and skill are required to inject the ganglion with alcohol as to remove it. No one without practising faithfully on cadavers for a long period of time and without a thorough knowledge of the deep anatomy of the parts should attempt the injection.

Harvey Cushing is especially bitter in decrying alcoholic injections into the ganglion. He has never deliberately injected the ganglion but records cases he has seen where failures of various kinds occurred. He cites the danger of the lower jaw becoming locked from alcohol getting into the joint or muscles; middle ear diseases with sloughing of the parts due to alcohol being injected into the Eustacean tube; facial paralysis, and other complications. In practically all of the cases cited by Cushing, an error in technic occurred by the operator and like any other operation unsuccessfully performed, unfavorable sequelæ ensued.

We do not assert that alcoholic injection into the ganglion is free of all complications. None of a serious nature, however, has occurred in our cases. In no case was the patient dissatisfied with the minor complications which were more than compensated for by the complete absence of their pain.

The opinion among medical men, judging from the statements made in the literature and physicians referring cases to us and our hospital interns, is that the relief of pain from ganglionic injections is temporary, varying from nine months to one year. We wish to correct this erroneous impression. We have never had a recurrence of any of our cases where the ganglion was successfully injected.

Hartel, in 1920,. reports fifty cases with no recurrence, his earliest case in that year was of seven years' duration. Byrnes in the same year reports four recurrences in a series of thirty cases. His earliest case at that time was of six years' standing. One was six and a half years; another was seven years; and all were free from pain. The remaining three cases were less than two years' duration.

We are repeatedly asked if injection of the ganglion fails, will the major operation be rendered more difficult. Alcoholic injection does not interfere at all with subsequent operation.

We never advise an alcoholic injection into the ganglion without first explaining the advantages and disadvantages of the various types of treatment used for the relief of tic douloureux. We do not urge it in preference to the major operation in every case. The decision must rest with the patient.

In old people with high blood pressure, kidney disease, etc., we feel that alcoholic injection should be given preference over any other procedure. In bilateral trigeminal neuralgia with a negative Wassermann reaction, alcoholic injection offers more with less danger than the radical operation.

The technic which we employ is that devised by Hartel. Local anesthesia or in apprehensive, nervous cases, analgesia with nitrous oxide or chloroform is used. The patient is placed in the prone position with the head slightly elevated on a sand pillow. A stiff needle graded in centimetres, of a slightly larger calibre than the one used by Patrick, is employed. The guard on the needle is fixed at six cm. from the point. The left index finger feels in the buccal cavity through the closed narrow passage between the coronoid process and the tubercle maxillæ. The needle is introduced into the cheek about two and a half cm. from the angle of the mouth and two cm. below. With the guidance of the left index finger it is directed subcutaneously between the mandible and the tubercle maxillæ directly upward until it meets with the hard smooth resistance of the sphenoid bone. The finger may now be removed from the mouth. The needle at this time will be at a depth of four cm. Before any further manipulations are made, it is essential to keep in mind the fact that a line drawn vertically upwards from the point of entrance of the needle into the skin will bisect the pupil of the eye if looked at from in front while if looked at from the side it will bisect the articular eminence of the zygoma. The needle is now pushed backwards and slightly upwards; the operation becoming more painful as we approach the third branch. After several tentative feelings with the needle, the resistance suddenly ceases as we penetrate into the skull through the foramen avale.

---

*Read before the Section on Medicine at the College of Physicians, Philadelphia.

We no longer feel any bony resistance, but instead what is quite characteristic on long practice, the elastic like resistance of the ganglionic tissue. The subjective symptoms of the patient vary greatly. Some suffer excruciating pain; others do not complain at all. In cases who have previously received extracranial injections of the third division, some difficulty is encountered because of the fibrous alterations around the foramen. The penetration of this scar tissue gives rise to pain and makes palpation along the bone more difficult. In these cases we depend exclusively upon the direction of the needle with its relation to the pupil and the articular tubercle. A trial novocaine injection using two per cent. solution will determine whether the ganglion has been reached. In about two minutes, if we are successful, analgesia occurs in the whole distribution of the trigeminus. If this action does not promptly follow, we are not in the ganglion, and experience alone will tell whether the injection should be repeated at a different depth or whether the needle should be withdrawn and the puncture done over.

In three of our cases dilatation of the pupil occurred with the injection of the novocaine. If our novocaine injection is successful, and the anesthesia is confined exclusively to the area supplied by the fifth nerve, we inject the alcohol. The alcohol should be injected drop by drop, close attention being paid to the eye movements of the patient and his subjective symptoms. The cannula is cautiously moved from side to side in order to inject as much of the ganglion as possible. A total of 2.5 c. c. of eighty-five per cent. pure alcohol is used. The cannula is rapidly withdrawn and the puncture wound painted with tincture of iodine.

The first few days following the injection, a careful record should be made of the extent of anesthesia obtained. If this area shrinks, i. e., if we find returning sensation, we can suspect that the ganglion has not been sufficiently infiltrated to give a permanent cure. These are the types of cases where the pain is likely to recur. At times this partial injection of the ganglion is indicated, but the patient must be warned that recurrence is more likely to occur.

COMPLICATIONS.

The most common complication is a hematoma of the cheek. This yields rapidly to cold compress treatment. Paralytic keratitis has occurred in about fifteen per cent. of the cases reported. We have had one ulcer of the eye which healed up under treatment leaving a slight scar. Septic meningitis has been reported by Hartel in one case. We have never seen this. The complications objected to by most men in criticizing the alcoholic injection are not due to the ganglion being infiltrated but are due to the alcohol being injected elsewhere.

We regret to report the loss of one eye, a year after the alcoholic injection. On account of the anesthesia of the cornea, the patient had been instructed to flush the eye daily with warm boric acid solution. She mistook spirits of ammonia for her boric acid solution and flushed the eye causing the deplorable result noted.

If proper care is taken to observe the effects of the trial novocaine injection, most of the untoward results reported will not occur, e. g., if ocular motor palsy follows the novocaine; if pain occurs in the ear; if the anesthesia is not complete in the distribution of the trigeminus, no alcohol is injected at this time and the position of the needle is altered or withdrawn and the puncture repeated when the effect of the novocaine has worn off.

Our attention has been called to the paralysis of the motor root following the injection of alcohol and devices have been suggested by A. Bleichsteiner, of Vienna, to overcome the deviation of the jaw caused by the paralysis. We have only seen one case with motor palsy after six months. As a general rule, motor paralysis clears up before the eighth month. Patients are unaware that it exists and it causes no inconvenience. Little or no atrophy of the muscles of mastication has been observed.

We are at the present time engaged in some experimental work on dogs, exposing the foramen ovale and injecting the ganglion with alcohol, in order to study the late effects of alcohol infiltrated into the ganglion. We are not as yet ready to report on these but are inclined to agree with the reports of Otto May, of London, and Charles Byrnes, of Baltimore. Degeneration of the ganglionic cells with fragmentation and disintegration of the nerve fibres of the spinal root occur in all cases. We agree with them that one injection of alcohol will not destroy the ganglion but it appears to cause, in a successful injection, chemical divisions of the sensory root.

FRIEDLANDER BACILLUS MENINGITIS

By Harold W. Jones, M. D.,
Assistant Physician, Philadelphia General Hospital,
and
W. G. Mitchell, M. D.,
Resident Physician, Philadelphia General Hospital,
Philadelphia.

The number of cases of Friedlander bacillus meningitis in medical literature is less than ten. As a matter of interest and because of its rarity, we make the following case report.

Case.—J. C., male, aged fifty-two, laborer, was admitted to the Philadelphia General Hospital, delirious and complaining chiefly of a severe headache. The history obtained from a friend, was that, five days previously, he had complained of a slight headache which increased in severity on the fifth day he had noticed that the patient was disoriented and showed marked incoherence of speech. As far as he knew the man had never been seriously ill but had always been a heavy drinker of intoxicating liquor. On admission to the medical ward the patient was combative, delirious, but not particularly oisy. The physical findings were as follows: Robust adult male, with slight cyanosis and no yspnea. Neck resisted flexion on chest. Some cervical ophthisthotonus was present. Nose and ears ormal, throat injected but no exudate present. Bilateral ptosis of lids, pupils dilated but mobile, eyes otherwise negative. The lungs were negative except for slight signs of moisture at the bases. The heart was regular, rapid; no enlargement or murmurs found. The abdomen showed a slight rigidity of the recti muscles. The extremities were negative xcept for isolated muscular twitchings.

The neurological findings showed: stiff neck, Kernig sign strongly positive in both legs, Brudzinski ign positive, Babinski sign positive in right foot, nd the Gordon sign positive.

The laboratory findings showed: Spinal fluid—urbid and under marked pressure, loaded with cells, 94 per cent. polynuclear, 6 per cent. mononuclear. The smear showed a gram negative extracellular bacillus (some with fatty capsule) four to five to he field. No meningococci were found. A culture showed typical Friedlander bacillus growth from four distinct specimens.

The blood: White blood cells 21,000, polymorphonuclear 90 per cent., small lymphocytes 8 per cent., large mononuclears 2 per cent., a culture was negative.

COURSE AND TREATMENT.

One hour after admission, forty c. c. of spinal fluid were withdrawn and thirty c. c. of antimeningococcus serum injected by gravity. The temperature was 103° F, pulse 125, respiration 28. Following the use of serum he was slightly improved. The next morning the fluid was again withdrawn and serum injected. Several hours later a cisterna puncture was made by Dr. Franklin Ebaugh and serum introduced. The pressure of the spinal fluid here was much greater than that withdrawn at Quincke's space.

At four p. m. that same day the patient became more comatose and showed marked cyanosis. The temperature was 105° F, pulse 160, respiration 40. He died at 8:15 p. m.

Unfortunately a postmortem was refused by the friends. We are indebted to Dr. Ross V. Patterson for the privilege of reporting this case.

1805 PINE STREET.

A CASE OF MENINGOCOCCUS MENINGITIS DIAGNOSIS BY MEANS OF COMPLEMENT FIXATION

By CHARLES H. NAMMACK, A. B., M. D.,
New York,
Captain, M. R. C., U. S. A.; Assistant Visiting Physician Bellevue Hospital, Instructor in Medicine Cornell University.

The following case is deemed worthy of report because it was a case of meningitis presenting unusual features and in which the usual methods of laboratory diagnosis failed and the diagnosis was only arrived at late in the disease by means of complement fixation tests on the blood and spinal fluid of the patient.

CASE.—The patient was admitted to the wards of the Fourth Medical Division of Bellevue Hospital on December 21, 1921, from the psychiatric wards, complaining of pains in the chest and fever. She was single, aged thirty-eight and a cook by occupation. The onset had come three weeks prior to admission with severe frontal headache. For a week before admission she had been vomiting. In order to relieve her subjective symptoms she imbibed considerable quantities of whiskey a beverage to which she was not unaccustomed both for medicinal and social purposes. It failed to relieve her and because of the resulting mental confusion she was admitted to the observation ward at Bellevue.

Her examination, including eyegrounds, ears and pelvis was negative except for furred tongue, flushed face, and slow pulse as compared to temperature 90° to 102° F. She was constipated. In spite of the absence of splenic enlargement or rose spots a provisional diagnosis of typhoid was made and blood culture and Widal were taken. On the 22nd and 23rd her temperature reached 104°, blood culture and Widals were negative, white blood cells 7,700, polymorphonuclears 78 per cent. hemoglobin 85 per cent.

Her condition remained the same for five days with elevated temperature and disorientation of a mild delirium. On the 28th it was observed that her neck was rigid with double Kernig. Lumbar puncture yielded cloudy fluid under pressure, 1200 cells 96 per cent. lymphocytes, 4 per cent. polymorphonuclears, no organisms by smear or culture, globulin two plus, no reduction of Fehling's. The gold chloride curve at this time was all zeros which was probably a technical error.

Spinal tap on the 30th showed 500 cells, globulin 2 plus, Fehling's negative, no organisms. Two diagnoses were considered at this time—encephalitis and tuberculous meningitis, with the latter as almost certain because of the absence of sugar from the spinal fluid. The Wassermann on both blood and spinal fluid were negative and there was no cranial nerve palsies so cerebrospinal lues was not considered. On January 2nd the spinal fluid was clear, no increase in pressure 256 cells 90 per cent. lymphocytes, globulin 1 plus, albumen 2 plus, Fehling's 0. No organisms present.

On the 3rd she was seen by the consultant from the neurological service who thought the case was one of meningism in association with a toxic condition most probably an alcoholic wet brain. The lumbar puncture done on January 5th showed clear fluid under pressure, 160 cells, 100 lymphocytes, globulin 1 plus, no reduction of Fehling's. The patient showed improvement, there was less rigidity and the temperature was lower. On January 9th lumbar puncture was again performed and yielded clear fluid without increased pressure, 96 cells, albumen 2 plus, globulin 1 plus, Fehling's 2 plus—the return of the reduction—and no organisms.

At this date the case was seen by Dr. Josephine B. Neal, Chief of the Meningitis Division, N. Y. Department of Health, who suggested the possibility of the case being a mild one of epidemic cerebrospinal meningitis. The blood and spinal fluid were accordingly tested for meningococcus fixation by Miss May Wilson in the Department Laboratory at Bellevue. The former yielded a strongly positive and the spinal fluid a weakly positive reaction. The agglutination tests were negative. The temperature reached normal on January 12th and a lumbar puncture done on this date yielded clear fluid, 103 cells, albumen 1 plus, globulin 1 plus, Fehling's 2 plus, gold curve 01122210000. From this time on the patient became steadily better and was discharged on February 21, 1922, as a cured case of cerebrospinal meningitis.

The unique features of the case were the late onset of meningeal symptoms and signs, the recovery under treatment which consisted only of repeated lumbar punctures without any serum therapy, and the making of a final and correct diagnosis without bacteriological evidence by means of complement fixation tests done on the blood and spinal fluid late in the course of the disease.

130 East Fifty-sixth Street.

Artificial Pneumothorax.—J. J. Perkins and L. S. T. Burrell (*Lancet,* March 10, 1923) show that artificial pneumothorax may be of value in conditions other than pulmonary tuberculosis, such as abscess of the lung, bronchiectasis, hemoptysis of unknown origin, and recurrent pleural effusion. In abscess of the lung the success of this procedure evidently depends upon the presence or absence of adhesions; where these are absent artificial pneumothorax is sufficient to effect a cure and render a more severe operation unnecessary. Considering the uncertainty of discovering the abscess cavity it is certainly to be preferred to drainage. When the abscess is superficial the presence of adhesions may lead under pneumothorax to its intrapleural rupture, necessitating drainage of the pleura. If the adhesions are widespread they may stand in the way of complete collapse and prevent success, necessitating thoracoplasty. But even so the authors advocate artificial pneumothorax as routine procedure, on the ground that it may be sufficient in itself and, where not, that the symptoms are relieved and the general condition of the patient improved, enabling him better to face the severer operation. Success in bronchiectasis depends on adhesions as it does in abscess of the lung.

Treatment of Typhoid Fever.—George S. Bel (*New Orleans Medical and Surgical Journal,* April, 1923) summarizes the treatment of the typhoid patient under the heads of general management, diet, hydrotherapy, chemotherapy, vaccine and serum therapy, and the treatment of special symptoms. General management includes a well ventilated room with good light, an efficient nurse, a comfortable bed, and a blood examination repeated every few days. The diet should be liberal, of easily assimilated foods. In selecting a diet one must remember. 1. That the carbohydrates, such as gruels, oatmeal, cream of wheat, hominy, crackers, bread, toast, mashed and baked potatoes, milk, sugar or lactose, should furnish half or more of the calories and lessen nitrogenous waste. 2. That protein destruction in typhoid fever is very high and can be avoided to a great extent by an average amount of sixty or seventy grams of protein in the diet. The proteins are supplied by milk, cream, eggs, beef juices, etc. Fats have a high caloric value and are of material aid, being mostly supplied by cream, butter and cocoa. 3. That vitamines are important. Here again milk is essential as it contains both water soluble B and fat soluble A vitamines; orange juice, lemon juice, tomato juice and other vegetable juices are beneficial. The diet should be varied daily and the food selected for each individual patient. Water should be given freely at definite intervals and in large amounts. Plain water is preferable to albumin water or lemonade. Hydrotherapy is the only logical febrifuge and affords the best means to reduce and control the temperature and to prevent the development of severe nervous symptoms. Whenever practicable the cold bath is always preferable, and the sooner it is instituted the better. A tub of sufficient length and width should be placed beside the bed and filled to three fourths of its depth with water at 85° F. in order to cover the patient up to the neck; the head should be supported by a rubber air pillow attached to the edge of the tub, and a rubber air cushion beneath the buttocks will make the patient more comfortable. The night shirt is removed, the patient covered with a sheet under which he is to be bathed, a stimulant, such as brandy, whiskey, or strong black coffee is administered, the body is wiped dry if perspiring, and a bit of cotton is placed in each ear. Then he is gently transferred to the bath by two attendants, one grasping him under the shoulder, resting his head on the attendant's arm, the other just below the knees, while the patient is asked to stiffen out. As soon as the patient is in the tub brisk friction should be applied to the whole body except the abdomen. Cold compresses, frequently changed, should be placed on the forehead. The bed should be prepared for his return by placing on it a double blanket and over this a warm, dry sheet, with hot water bottles at the foot. The patient is lifted from the tub into the bed, the warm, dry sheet folded over him, a fold being passed between each arm and the side of the body and between the legs so the skin surfaces shall not come in contact, and thoroughly dried by being rubbed over the sheet and the blanket then wrapped about him. At the end of ten minutes he is taken out of the sheet, rubbed dry, gown and bed clothing replaced. When this method cannot be employed the wet pack may be used, or when this also is impracticable, the entire body, except the abdomen, may be rubbed briskly with cold water. Drugs are of little value in uncomplicated cases. Massage of the lower limbs during the course of the fever renders the patients capable of walking earlier than usual. Vaccine and serum therapy, while theoretically correct, has not yet proved of practical value. Special symptoms: Thorough evacuation of the bowels early in the course, best with castor oil. Then a daily evacuation by means of enemata or mineral oil if necessary. Diarrhea and tympanites can usually be overcome by regulating the diet, withdrawing sugars, cream, fruit juices, jellies. If this fails recourse is had to usual methods. When hemorrhage occurs the first essential is absolute rest and withdrawal of all food. Perforation demands immediate operative intervention, if possible under local anesthesia. The patient should not be allowed to sit up in bed until he has been free from fever from three to five days.

Proceedings of Societies

NEW YORK NEUROLOGICAL SOCIETY

Four Hundred and Fifth Regular Meeting, Held on May 1, 1923.

Dr. E. G. Zabriskie, president, in the chair.

ADDRESS OF EDWIN G. ZABRISKIE, M. D., PRESIDENT ELECT OF THE SOCIETY.

In this present day world of constant endeavor to ncrease efficiency in all direction, but chiefly along he lines of production, we at all times encounter the efforts of the medical profession to contribute their share in this work, not only by improving the health of the individual, but also by preventing disease states. That we as neurologists and psychiatrists come in for a heavy share in the responsibility of preventive medicine cannot be doubted if one stops o consider that today there are 250,000 patients in hospitals for mental diseases in this country; that 0,000 are admitted to these hospitals annually; that he cost of maintenance for those suffering from mental diseases is about $75,000,000 each year, while he economic loss to the United States each year on account of mental diseases is over $200,000,000.

Before the war our most intensive thought was applied chiefly to the problems of prophylaxis, treatment and custodial care of the insane, the feebleminded, the delinquent and the criminal. Years of patient effort had succeeded in enlisting the sympathetic cooperation of public minded men of diverse occupations and intellectual training, for the purpose of attacking these problems, because of the social economic wastage they represented. A comprehensive program for intensive study of the situation throughout the country was inaugurated by the National Committee and gratifying results had already been obtained. The entry of the United States into the war, however, interrupted this program temporarily, but its loss was more than offset by giving us a magnificent opportunity to arouse the attention of the community at large to the great numbers of young men eliminated during our hurried assembling of soldiers, because of pathological constitutions or temperamental instability as well as organic nervous disorders, which rendered them unfit for military service. We are now beginning to profit by this lesson, for we realize as never before the almost staggering proportion of unstable persons in this country, many of whom never reach custodial care, but who nevertheless represent a tremendous decrease of steady production, who at least in episodic reactions are potentially insane or are potential criminals. These facts have been accorded due significance in the economic and etiologic problems of neuropsychiatry and are furnishing a still greater stimulus for the prevention of disease.

One might say that it was hardly necessary to formulate so obvious a truism, that the proper place to begin the investigation of the preventive side of the problem is during childhood, since science teaches us to search the very beginning of all morbid processes for their causes. This has long been the practice in the study of insanity and of criminology, especially since we have undertaken the investigation of personality makeup, as a glance at the treatises on mental diseases and the studies in juvenile delinquency and truancy will confirm. But now an imperative demand for a more searching investigation of the milder conduct disorders and maladjustments of childhood, the nervous child with tics, speech defects and other evidences of instability becomes manifest, and today we see an extensive movement under way in many widely separated parts of this country, which embraces the study and treatment of all functional nervous disorders of childhood, and covers a field, the limits and possibilities of which are almost boundless. Problem clinics, mental hygiene clinics for children, school clinics, clinics connected with the courts are springing into existence from coast to coast, and we can foresee the foundations laid for a composite picture of the abnormal individual from childhood on, which will perforce include the anthropomorphic, physiological, personality and emotional makeup, the environment and all other factors which might influence the development of the individual.

Even some of the psychologists are beginning to recognize that other factors than intelligence quotients are necessary for the complete understanding of the person. Thus in 1914 Wallin suggested that, "Just as soon as a child shows evidence of abnormality, incorrigibility, etc., he should be examined by a psychoeducational clinic which should also afford a medical, hereditary and sociological examination."

The schools furnish a wonderful opportunity for study of these abnormalities either by the group method or individually. The observations of A. J. Pillsbury that ninety per cent. of criminals begin their careers as truants, show what a wealth of material we have practically at our door. On a conservative estimate, from two to four per cent. of retarded children in the schools are idiots, imbeciles, morons, border cases, epileptics, neurotics and psychoneurotics. From fifteen to thirty per cent. grade all the way from border line or seriously backward to merely dull or slow progress pupils. Fully one third are pedagogically retarded when measured by age-grade standard, and about two per cent. suffer from some form of speech defect. As there are approximately 6,000,000 pupils in the United States the full significance of these figures becomes apparent to those of us who participated in the army eliminations.

Someone has said that one of the most striking if not the most important lesson of the great war was that temperamentally the human race had not changed in any essential feature since the very earliest times. There is much evidence to support the statement and truly we seem to find the same savagery, wanton destruction, wholesale discarding of personal responsibility, mass hysteria among soldiers and civilians alike, that characterized all former conflicts. Furthermore, each nation displayed the emotional reactions that had characterized it since its inception or in other words ran true to its national form. If the above statement contains the elements of truth as I surely believe it does, one must turn for its explanation to that elusive combination of so-called primitive instincts, unconscious strivings, inhibitions, impulses, moods and emotional traits that contrive to form what we are pleased to call personality, character or individual makeup. Although long ago Herbert Spencer uttered his belief that the whole of life is an adjustment, a continuous adjustment of inner to outer relations, it is only within relatively recent times that sociologist, psychologist and psychiatrist have turned from the study of groups and their classifications to intensive work on the individual and his reaction to environment. Thanks to the illuminating and clarifying studies of Hoch, Freud, Janet, Bleuler and others, we now have at least a working method of approach to the problems of personality makeup, although it is not the purpose of these remarks to do more than point out some of the current ideas. To be sure they are chiefly founded on behavioristic reactions, at least from the viewpoint of MacDougall, who, as the late lamented Southard puts it, has begun to study man's inner relations as they touch society and from the viewpoint of the sociologists who are endeavoring to carry society back to certain springs of action in the individual mind. To the MacDougall school character is the result of habit formation or instincts which are amenable to selfcontrol and selfdetermination. The psychoanalists, while dealing chiefly with psychopathology, look at personality in terms of sex determinism, conflicts, sublimations, repressions, unconscious strivings, organ representation and the like.

A glance at the most recently compiled endocrine charts will show that a definite place is accorded emotional traits, psychic variability and sexual characteristics, whether they be inversions, heterosexual or hermaphroditic features. Some of the more fanciful of this group of specialists have gone the length of constructing personality types; thus we have the pituitary type who is aggressive, precocious, calculating, selfcontained, the pituitary inferior mentally dull, apathetic, sluggish, poor self control, emotionally unstable, easily discouraged. The hyperthyroid: restless, talkative, liable to anxiety states and vasomotor instability. The hypothyroid: dull, apathetic, prone to all grades of depression, thymic. The morally irresponsible with a tendency to drug addiction, homosexual practice, suicide. The gonodal: introverted, shutin, sex and emotional infantilism or the eunuchoid state.

One even attempts to link the fundamental instincts with the internal secretions; thus we read that the two most important instincts which in the complexity of their sublimations have created most of the institutions of society: the maternal (social and creative), and intellectual curiosity (constructive and acquisitive tendencies) are connected with proper function of the pituitary.

In closest relation to the thyroid are the instincts called, by MacDougall, selfdisplay and selfeffacement, exaltation, boasting, exhibitionism or depression, selfreproach, etc. Thyroid activity is also expressed in sensitivity, i. e., the ability to discriminate between different grades of sensation and energy. If poor memory goes with the kind of thyroid inactivity seen in cretins, we may deduce that good memory thyroid is associated with inactivity; it works by increasing the conductivity of the brain.

At all events we are entering a period of research in childhood which should constitute the most extensive biological laboratory experiment the world has ever seen. It will need many years of painstaking, patient collecting of data before the results can be known and unfortunately most of us present will have passed on without more than a conjecture of what they will be.

At a small gathering not long ago it was my privilege to listen to a highly diverting semihumorous outline of plans for the establishment of a parentorium, i. e., an institution controlled by the state to which parents having difficulty in the management of their children could be committed. The basic idea of the scheme was a reformatory one which had in view the inculcation of a proper sympathetic insight into the real difficulties of childhood. Fantastic as the idea may seem, it nevertheless strikes deeply at the root of so many conduct disorders in childhood, as anyone familiar with mental hygiene literature must know. The instance of a mother's despair over the incorrigibility of her little girl, when she herself made promises of candy, clothes, etc., as inducements to secure necessary trips to the doctor or dentist or something equally unpleasant, but with no intent of fulfilling such promises, and allowed the child to see her pilfer money from her sleeping husband's clothes is by no means uncommon. Locking a six year old child in a dark closet for half an hour is no way to cure him of his fear of the dark, nor is the practice of holding the thumb of a four year old baby against a hot stove a safe method of correcting thumb sucking. The literature on delinquents likewise abounds with comments on unintelligent handling of children through lack of proper insight, example or energetic measures sufficient to adequately carry out recommendations made by competent persons. Frequently the home environment is frankly impossible either through sheer physical inability on the part of one or both parents due to malnutrition or some bodily disorder to cope with the problem. On the other hand they may be frank neurotics, psychoneurotics, psychopaths of one sort or another who are thereby not only totally inadequate to handle the situation, but on the contrary they are often the most important factors in the creation of these situations. Imagine for instance the possibilities for the production of unhealthy traits in a little girl of eight years whose home life is the constant scene of quarrels between a father who is aggressive, easy going, possesses no ideas of discipline, and accedes constantly for the sake of peace and quiet to the whims of a mother who is profoundly egocentric, headstrong, a day dreamer, hypersensitive and periodically addicted to morphine.

Subdural Effusion and Hydrocephalus.—Dr. Wilder G. Penfield, (by invitation), presented a case of a little boy with increased intracranial pressure after otitis media. This had progressed to blindness on admission to the Presbyterian Hospital. By means of cranial pneumograms, pressure determinations and chemical and cystological study of the fluids, it was determined that there had been an effusion of fluid into the subdural space and that perhaps secondary to this, there was a moderate degree of ventricular dilatation. As a result of successive dural punctures the vision returned to a large extent and the other evidences of cerebral compression disappeared. The speaker suggested hat subdural effusion would explain the not infreuent association of otitis media with papiledema.

Dr. C. A. Elsberg discussing the case presented y Dr. Penfield said it was interesting and rare. ubdural effusions were rare excepting after trauma, nd an effusion as a result of an inflammatory process was very rare indeed. The x rays presented by Dr. Penfield showed the extent of the subdural effuion and that the ventricular system was open.

The case is also very interesting from the viewpoint of the blindness. For years I have been telling he students that, if an individual is blind from apilledema, the vision can never be restored. I ave tried to save some vision by early operation, nywhere from four to twenty-four hours after the complete loss of vision had occurred, but was never ble to save the patient's eyesight. Recently, howver, I had a patient who was entirely blind from papilledema but in whom considerable vision returned after removal of fluid by ventricular puncure. Dr. Penfield's case is another one of this ind. Dr. Penfield's case shows also how much inormation can be obtained from a careful study of he x ray plates after air injections.

Dr. I. Abrahamson said that it was very likely hat in this case the blindness was due not to the apilledema, but to collections of fluid covering and ffecting both calcarine areas. The child appeared o have hemianopsia at the present time.

Dr. W. G. Penfield (in closing) had nothing to dd except that it is very difficult to be sure whether r not any hemianopsia is present in a child of this ge. His mother has noticed that he holds objects up to one eye for inspection in preference to the other. The corresponding optic disc is less pale than hat on the other side. I have assumed that this xplains his movements rather than any hemianopsia.

Work of Demonstration Clinics Conducted by Division on Prevention of Delinquency of Naional Committee for Mental Hygiene.—Dr. V. V. Anderson, of New York (by invitation), said that more than half of the children that passed through he juvenile court showed physical and mental disabilities that are fundamental factors in their delinquent conduct. The disposition of their cases, without an adequate knowledge of the social implications of those conditions, merely invites failure so far as he adjustment of the child is concerned. Certainly ntelligent treatment without such knowledge is impossible. While a certain percentage of the children presents serious problems, the great majority of them are not to be thought of in terms of the usual medical classifications but as examples of childhood difficulies that have their origin in the home, the school, or other situations in which parents, brothers and sisters, teachers and playmates have an important part.

In the particular conduct of the child we will find the rôle his personality plays in adjusting itself to ife's situations. This view of behavior has a personality reaction in the effort of the child to adjust himself to his environment, by no means excludes consideration of the values to be attached to serious constitutional conditions both inherited and acquired. The importance, however, of feeblemindedness and grossly abnormal mental conditions is not such as we were led to believe from earlier investigations.

Real progress will be made through a better understanding of the children's personality and the influences from within and without that mould it and make it what it is. Our studies have shown that practically all of the delinquent children that pass through the juvenile courts are also public school problems. Effective preventive work means the application of more scientific measures in understanding and solving the problems of the children before they get into court, while they are in the school and at home.

Dr. Thomas H. Haines said that these systematic demonstration clinics which the Division on the Prevention of Delinquency of the National Committee for Mental Hygiene is stationing in various cities, he regards as outposts for the demonstration of what the social engineer and the psychiatrist can do in the study of the problems of many unfortunate boys and girls.

Miss Elizabeth Farrell remarked that the type of work described by Dr. Anderson, with modifications that we know to be desirable, has been carried on by the Board of Education of this city for the past twelve years.

Dr. L. Pierce Clark fully approves of Dr. Anderson's work in all its bearings. Beyond the immediate practical value of Dr. Anderson's results is the highly important effort to solve what may be done to modify human nature either in its inherited or acquired pattern. This larger problem is usually embraced under what we designate as personality, while character is the term that perhaps may be limited to the uses to which this innate personality is put in the process of life adaptations. Personality perhaps may not be changed, or only so slightly as to be negligible, while character lies at the very core of our social adjustment and may be signally changed with the beneficient results which Dr. Anderson has already reported.

Dr. Sanger Brown spoke of some other interesting studies which Miss Theis, of the State Charities Aid Association of New York, has been making. She has records of about 950 children who have been placed out in homes by that society. Miss Theis's findings indicate that despite their bad or uncertain heredity these children are not very different from children from normal homes. Many of them have now reached the age of eighteen years and over. There is not a high percentage of insanity among them; there is not a high percentage of mental defect, and there are not many delinquents in the group. This is a hopeful aspect of this whole problem of child welfare in the case of dependent and neglected children.

Dr. S. R. Leahy mentioned the fact that 1,600 children were surveyed at the Protectory last summer, according to intellectual percentage; eighty-five per cent. were of average intellect, about five per cent. were subnormal, and the rest of the group superior. He also found that third offenders were all practically four years or more back in grades. He stated that Miss Farrell is correct and that school is the first adaptation. The child is forced to meet others outside the family. Here he feels that there are other children who have rights. If he is successfully placed here, it will be a real prevention of further defects.

Abstracts from Current Literature

NEUROLOGY.

The Present State of Experimental Research in Herpes and Encephalitis. — Ernst Lauda (*Wiener klinische Wochenschrift,* March 29, 1923) finds that febrile herpes and herpes of the genitals and of the cornea have the same etiology, which is a uniform, living, filterable virus. Different authors have been enabled to cultivate easily viruses from patients with encephalitis, which showed the same characteristics in animal experiments and immunologically as the virus of febrile herpes, with which they apparently are identical or closely related. The theory of their identity of Doerr and Schnabel, which is based upon this fact, does not seem to have been contradicted up to this time. The author's own investigations point in favor of this theory of identity, insofar as the same general symptoms were observed in rabbits after inoculation with the herpetic and encephalitic inoculation and insofar as it was demonstrable that the changes in the brain of rabbits are also identical.

The Relationship of Epidemic Encephalitis to Herpes Febrilis and to Influenza.—As a result of a series of experiments, R. Doerr and W. Berger (*Schweizer medizinische Wochenschrift,* August 31, 1922) arrived at the following conclusions: 1. Two new strains of encephalitic virus (Basel II and Basel III) could be isolated by subdural inoculation of the brain emulsion in rabbits from the brains of two clinically and pathologicoanatomically diagnosed cases of epidemic encephalitis (lethargic). 2. These reacted in a typical manner on the cornea and the central nervous system of the experimental animals. 3. One of the strains was used for experiments in crossed immunity with the virus of herpes febrilis, with the result that the similar immunizing powers of encephalitis and herpes febrilis were demonstrable. 4. The encephalitic virus was not demonstrable in the blood of uncomplicated cases of influenza, following its reinoculation into the rabbit's cornea, either in the beginning of the disease or at the height.

A Cerebrospinal Fluid in Disease of the Fundus.—W. J. Wellwood Ferguson (*British Medical Journal,* December 30, 1922) shows that the condition of the cerebrospinal fluid is well worth examining in many cases, especially that of young adults suffering from diplopia, optic atrophy, or retrobulbar neuritis. He considers the colloidal gold reaction of undoubted value as indicating the first definite sign of organic disease of the central nervous system; inasmuch as some of these cases later develop into frank disseminated sclerosis or neurosyphilis its value in early diagnosis and particularly in prognosis and treatment is considerable. Furthermore, it also may enable one to say whether a transient diplopia is or is not purely functional and may help to differentiate cases of retrobulbar neuritis and optic atrophy, indicating those in which the condition is part of a more general nervous disorder, and more especially those which may be followed after a considerable period by disseminated sclerosis.

Acute Cranial Injuries.—H. Jackson (*Surgery, Gynecology, and Obstetrics,* April, 1922) from clinical and experimental observations, concludes:

1. In most acute injuries of the brain, the cerebrospinal fluid pressure is a fair index as to the severity of the lesion. Dependable prognosis can be made by any increase or decrease of this pressure.

2. A new clinical classification of injuries of the brain based upon cerebrospinal fluid pressure alone, as shown by the mercury manometer, is superior to the accepted classification of concussion, contusion, and compression.

3. The pathogenesis of acute injuries of the brain demonstrates that the principal effect of the edema of the brain and hemorrhage is to interfere with the absorption of cerebrospinal fluid by the usual paths; this sets up a vicious circle causing further pressure on the brain by the accumulating fluid in the basal cisterns below the tentorium cerebelli and in the lateral ventricles which presses the brain upward against the dura and produces cortical anemia. The cortical anemia, if unrelieved, quickly leads to gliosis causing lasting changes in the character, disposition, and mentality of the patient, if he recovers from the brain injury.

4. The relief of the increased pressure on the brain and the reestablishment of the normal path of absorption of the cerebrospinal fluid can be obtained by repeated lumbar drainage—which in acute injury cases is absolutely without danger.

5. Lumbar drainage is superior to subtemporal decompression in relieving pressure below the tentorium cerebelli and has the further advantage that it leaves no mutilating skull defect. The use of concentrated salt solutions intravenously lowers cerebrospinal tension but does not remove blood.

Diagnosis of Intracranial Abscesses in the Ambulatory Period.—H. Aboulker (*Presse médicale,* June 3, 1922) notes that large extradural abscesses in the frontal, temporoparietal, and even cerebellar regions may not produce any symptoms, being only accidentally discovered in the course of resection of bone involvements or upon investigation of the dura. Consequently extensive and deep investigation of the dura must always precede puncture of the brain and should, furthermore, form part of the first stage of the operative intervention where the least suspicion of a reaction on the part of the meninges and brain exists. The classic symptomatic picture of brain abscess is frequently wanting even in the presence of extensive destruction of the temporosphenoidal lobe, cerebellum, or both. This symptomatic picture attaches rather to an aseptic meningitis with high pressure, which, indeed, sometimes coexists with abscess. These two disturbances are very similar, yet can be differentiated contrary to current opinion. Brain abscesses yield two constant and early signs, viz., headache with clouded mentality and an altered disposition. These cases should be looked for and subjected to operation during the ambulatory stage of their course, which is very prolonged, and at the time when mental clouding and depression and altered disposition begin to be manifest, before the stage of somnolence and stupor. General anesthesia, particularly chloroform, is to be avoided in cases of suspected meningoencephalic complication; local anesthesia by procaineadrenaline is, on the other hand, very satisfactory in these cases.

Tetanism in Meningitis.—H. Batty Shaw and Cyril Dee Shapland (*British Medical Journal,* February 3, 1923) find that meningitis may provoke tonic spasm of the facial muscles, producing risus sardonicus, of the muscles of the neck and of the abdominal wall; that the spasm may be constant, lasting for hours and even days; and that the spasm may become increased by irritation (nasal feeding, etc.), the patient remaining conscious throughout the illness. The view, formerly held, that such features constitute a clinical picture of undoubted tetanus must now be abandoned, because the disease may be accurately imitated by meningitis. The term "meningism" would be appropriate here as there is no inflammation of the meninges. The authors propose the term "tetanism" to fix the identity of those clinical conditions which simulate the very special form of toxemia produced by the growth of Bacillus tetani at some spot distant from the central system, and which may be dependent upon meningitis developed as a result of infection of the central nervous system by organisms quite different from Bacillus tetani.

The Nitrogen Method as an Aid to Differential Diagnosis in Mental Diseases.—R. V. Stanford (*British Medical Journal,* June 10, 1922), in view of the fact that the Wassermann and Nonne-Appelt reactions are not absolutely reliable in the diagnosis of general paralysis, advances an additional laboratory method of diagnosis. There is no choline or ammonia in the cerebrospinal fluid, but if the latter is taken from a case of general paralysis postmortem, decompositions occur with the production of 1, a substance giving the alkaloid reaction of choline although it is not choline, and 2, the ammonia salts form a platinichlorid distinguishable from choline platinichlorid only by polarization. The freshly obtained cerebrospinal fluid carefully handled does not show either of these two products.

The products of degeneration during life in general paralysis can be demonstrated by the following method: One c. c. of cerebrospinal fluid is heated with fuming sulphuric acid, the mixture is diluted with water, made alkaline and distilled into a series of Nessler cylinders where the ammonia is estimated by Nesslerization. The author calls the nitrogen number the number of hundredths of a milligram of total nitrogen per c. c. This number usually lies below twenty in cases of mental disease other than general paralysis and almost always above twenty-five in cases of general paralysis. In the graphic mode of representation illustrated, there is an ambiguous area between the numbers twenty and twenty-six. Whereas the nitrogen method not only reveals but measures the products of excessive catabolism in brain tissue, it does not indicate its cause; it also shows up other diseases like brain tumor, meningitis and cerebral hemorrhage, but these diseases are easily excluded by clinical methods. Normal cerebrospinal fluid shows total nitrogen values between fifteen and twenty-two. The approach or occurrence of death leads to a large increase in the nitrogen contents of the cerebrospinal fluid, but postmortem determinations are valueless. The differentiation between mania, melancholia and other common mental disorders, or between these and cases not insane, is impossible. The nitrogen values also indicate whether a condition is of a progressive or stationary nature. It was also shown that there is a difference between secondary dementia and mere senility, although the underlying physical condition is undiscoverable by any method.

Further Observations Upon External Hydrocephalus.—Cecil E. Reynolds (*British Medical Journal,* June 17, 1922) found that congenital external hydrocephalus shows certain differences of character from the acquired form. The congenital variety is frequently associated with microcephaly because of the diminution in expansile pulsation; the ventricles do not enlarge to any extent but the brain shrinks, the skull is arrested in its development and the subarachnoid and subdural fluids stay abundant because the foramina of Magendie, Key and Retzius are patent and often there is no tela choroidea or arachnoid covering the fourth ventricle. Many patients have normal sized heads but appear mentally defective with some bulbar paralysis and varying degrees of spastic or flaccid diplegia or pantoplegia. The legs are invariably affected more than the arms because the pressure is greatest at the leg centres at the vertex. An opening in the dura in this region, unless promptly closed, is almost inevitably fatal in these cases because of the rapid loss of cerebrospinal fluid. The safest approach is a graduated suboccipital deduralization in chronic cases; supratentorial measures are sometimes required subsequently. The flaccid type of this disease often has a better prognosis than the spastic. The congenital cases do not have fits; acquired cases always, even though the disease is acquired a few days after birth.

The acute specific diseases, especially tonsillar infections, as well as birth trauma, are the most usual causes of primary external hydrocephalus. The so-called *ex vacuo* accumulations of fluid are local collections of fluid in certain cases, but when extracerebral fluid is general, the brain has shrunk because the fluid accumulated and the fluid does not accumulate to fill the vacuum left by an otherwise unaccountable atrophy of the cortex.

Infectious Motor Paralysis in Young Rabbits.—J. Homer Wright and Eugene M. Craighead (*Journal of Experimental Medicine,* July, 1922) made an unsuccessful attempt to infect young rabbits and guineapigs through intracerebral inoculations with material containing in all probability the virus of infantile paralysis. However, a paralytic disease occurred which was spread among young rabbits apparently by simple contact. The disease was associated with a large organism which it is believed has not been hitherto described. Clinically the rabbits show a persistent drowsiness followed in most cases by tremor shortly before paralysis develops, which may be slight or marked, general or localized. The mortality is high. It was possible to reproduce the disease in other rabbits by intracerebral inoculations of sedimented urine, and also of cord emulsions from sick rabbits. The presence of the organism in the urine readily accounts for the spread of the disease by contact. Attempts to transmit the disease through the bites of bedbugs and mites were negative. Histological examination of the rabbits showed a wide distribution of the organism through the organs of the affected animals, with active destruction by the organism of the nerve cells of the spinal cord, which supplies the explanation for the paralysis observed clinically. The nature of the organisms has not yet been determined, but the authors suggest that it is probably an intermediate stage in the life of some protozoan parasite.

Periarterial Injections of Alcohol in the Treatment of Senile Gangrene.—W. Sampson Handley (*Lancet,* July 22, 1922) reports two cases of senile gangrene to illustrate a new method of producing vasoconstrictor paralysis unattended by the objections which are associated with the sympathetectomy of Leriche. In the latter operation, local constriction of the artery occurs and a period of low circulation (up to fifteen hours) precedes the onset of vasodilator symptoms which last three to four weeks. The initial extreme vasoconstriction lasting for fifteen hours may be dangerous in existing or threatened gangrene and the period of vasodilatation is all too short for the separation of a portion of the foot. In periarterial alcohol injections, there is no initial period of diminished circulation and the results of vasodilatation appear at once, without any temporary aggravation of the condition which the operation is intended to cure; no local contraction of the artery occurs at the site of the injury. In sympathectomy, the local injury of the muscular coat of the artery, causing a local muscular spasm, produces the initial constrictor symptoms, which is undesirable and avoidable with the method of alcohol injection. The latter method is also much simpler than excision of a lamina of the arterial coats. It should possess even greater value in the prevention of senile gangrene than in the treatment of gangrene which has already taken place. It may also prove to be applicable in other ischemic conditions of vasomotor origin.

Some Clinical Manifestations of Tabes Dorsalis.—Gordon Holmes (*British Medical Journal,* January 13, 1923) states that the diminution, complete loss, or alteration of sensibility to pinpricks in the distal portions of the lower extremities, the thoracic zone, the radial borders of the arms and the central portion of the face are the most common, the most definite and the most characteristic physical signs of tabes dorsalis. Such findings are often present when the knee jerks and the pupillary reactions are normal and before ataxia or other symptoms develop. This loss of sensation in these areas is a dissociated one, the different modalities being affected in different degrees, or some forms only may be disturbed; touch is frequently intact on the chest and face at least and the affection of thermal sensibility is inconstant. Dissociated analgesia of similar distribution is encountered in no other disease which enhances its value.

Alkali Reserve in Epilepsy.—S. Kjelland Mördre (*Norsk Magazin for Laege videnskaben,* August, 1922) concludes from his analyses of the blood and urine of epileptics that the alkali reserve in these cases measures a little higher on the average than it does in normal cases. This alkalosis may hardly be looked upon as anything more than an indication of the hypothetic toxin of epilepsy, if this theory is admitted. The fact that in one case the administration of fifteen gram bicarb. natrium increased the alkali reserve from sixty-nine to seventy-one per cent. of the carbon dioxide capacity in one hour, without any spasmodic or other reaction on the part of the patient would seem to refute the theory that alkalosis per se could be the cause of the attacks. In most of the cases observed by the author, the urine showed a normal NH_3 content, and in one case even a very low NH_3 content immediately preceding an attack. These findings were in opposition to the usual statistics, which report pathological quantities of NH_3 in the urine, particularly during the period immediately preceding the attacks. The author, however, admits that his limited material may account for this discrepancy in findings.

Neurosyphilis With Severe Laryngeal Crisis: Tracheotomy.—John W. Leitch (*British Medical Journal,* June 17, 1922) reports a case in which the symptoms point to an irritative cortical lesion as the most likely cause of the severe laryngeal crisis. A centre for the adduction of the vocal cords has been demonstrated in each cerebral hemisphere at the anterior part of the lower end of the ascending frontal convolution. Irritation of either centre results in adduction of both cords, while abduction is rather governed by the lower centres in the floor of the fourth ventricle.

A man, thirty-five years old, was found suffering with such severe respiratory embarrassment and cyanosis that a low tracheotomy was done. Unconsciousness had already set in and the tracheotomy was followed by convulsive movements of the arms and legs, but later consciousness returned. A superficial ulcer was found round the frenum of the tongue. Direct laryngoscopy showed the movements of the anterior parts of the cords to be normal but the posterior third moved sluggishly and did not approximate fully. The mucosa of the arytenoids and false cords was red and edematous. Recovery followed. Fifteen days after admission the patient showed a gumma in the left anterior pillar of the fauces and one week later another gumma in the sternomastoid muscle; both subsided within a week. Owing to the presence of the usual classical symptoms, syphilis was diagnosed.

The general convulsions may be explained by the extension of the irritation to the neighboring centres. The appearance and rapid subsidence of gummas elsewhere suggests a cortical lesion, while the paucity of localizing symptoms suggests a gummatous formation in the membranes of the cortical centre rather than in the brain substance. The possibility of an early tabes must also be considered; such crises are the early symptoms of this disease and may occur several times a year or oftener, but this does not negative the possibility of the laryngeal crisis being due to an irritative cortical lesion, caused by gumma.

The Occurrence and the Differential Diagnostic Significance of Tenderness of the Phrenic Nerve (Mussy's Point) in Diseases of the Abdominal Viscera.—F. Högler and K. Klenkhart (*Wiener Archiv für Innere Medizin,* October 15, 1922) draws the conclusion that the demonstration of Mussy's int of tenderness is important not only in thoracic ocesses but also in abdominal diseases, especially if e tenderness is over the right phrenic nerve. If is is found sensitive, the first condition to be ought of in the presence of negative findings in e lung is an inflammatory process in the region of e gallbladder. The best location to look for ussy's point is between the two heads of the ster- cleidomastoid muscle, where the phrenic nerve rns around the anterior scalenus muscle into the eper tissues and where it lies most superficially. ight pressure suffices to elucidate the tenderness.

The Results of Treatment in Syphilis of the entral Nervous System. — Reginald Hearn *British Medical Journal,* July 8, 1922) reviews one undred cases of syphilis of the central nervous sys- m. Nervous syphilis is much more likely to follow papuloerosive primary lesion. In this series of ses sixty-four showed no trace of any scar, thirty- ree showed only a slight and almost invisible scar; o showed scars typical of a papuloulcerative chan- e and only one case showed a scar of a primary anulating chancre. The more inconspicuous the ancre, the greater the likelihood of the develop- ent of late nervous symptoms. Seventeen cases owed the meningeal, interstitial, or late secondary pe of lesion, of which two were "neurorecurrences" llowing the use of arsphenamin.

All of these cases were restored to normal health, dged from the serological and pathological view- ints. Patients with tinnitus aurium were never lieved of this symptom. The subjective symptoms those who were afflicted with degenerative or renchymatous lesions were much improved by eatment. Of eighty-three cases treated, none owed any alterations in physical signs or the patho- gic picture of the cerebrospinal fluid and the lat- r was no criterion in determining whether a patient ith degenerative neurosyphilis required treatment. eneral paretics were improved and the onset of in- nity was postponed provided the treatment was gun before they became obviously stupid and in- tuous; the treatment was worse than useless and even hastened the fatal termination if the late age had already developed.

True Nature of Coxa Plana.—Calot (*Bulletin l'Académie de médecine,* April 24, 1923) main- ins that coxa plana is one of the radiographic ap- arances representing a special dystrophy of spinal cerebral origin which is the cause of congenital slocation of the hip, distinct or merely incipient. is never seen in normal hip joints, i. e., hip joints ee of congenital deformity. Conversely, in all hip ints exhibiting such deformity, coxa plana may pear at any time during the period from three to xteen years, in which osteogenesis and calcium etabolism are most active. In some instances the set of coxa plana is traceable to such causes as falls other traumatisms, overstrain, or intercurrent dis- ses that impair muscular tone. In all cases of coxa ana one can discover upon careful x ray and clini- l examination evidences of a dystrophic condition tending from the sacrum to the toes and involving e bones and soft tissues. There are many points of milarity between the congenital dislocation and coxa ana cases and tabetic joint disease and syringomye- . All are of central nervous origin, and all show a paradoxical combination of atrophy and hypertrophy of the hips in the same individual, or even in the same hip, the two processes existing side by side. All are frequently bilateral, bacteriologically negative, and unreproducible experimentally by factors acting on the hips alone. While a traumatic dislocation is possible, the true lesions of congenital luxation or coxa plana never result. Such lesions could only be produced by first inducing a hydrops of the cord or brain or a hydromyelia such as that found in Lannelongue's autopsies. Coxa plana may be observed either in reduced or unreduced congenital hip dislocations. Irregular pressure of the dystrophic bone surfaces may be the cause of the condition.

Sugar Findings in Normal and Pathological Spinal Fluids.—A. G. Kelley (*Southern Medical Journal,* June, 1923) has studied the sugar content of normal cerebrospinal fluid, the effect produced on this content by the inoculation of colon bacillus, staphylococcus aureus, pneumococcus, and meningococcus, and, on rabbits, the effect produced on the sugar content by large intravenous injections of dextrose. He then studied the sugar content of the cerebrospinal fluid in various diseases, but especially in syphilis of the nervous system. From the results of his observations he thinks it justifiable to conclude 1. That the sugar content of cerebrospinal fluid is decreased in untreated cases of syphilis of the nervous system, in meningitis due to the meningococcus, the staphylococcus aureus and the pneumococcus, and in moribund cases. 2. That as cases of syphilis of the nervous system are treated, the sugar content gradually approaches the normal and on this account repeated estimations of the sugar content of the cerebrospinal fluid in these cases may possibly be of prognostic value. 3. That there is sufficient evidence to warrant the opinion that the Treponema pallidum, when present in the cerebrospinal fluid, utilizes the sugar normally present in the fluid.

Foul Odor as an Epileptic Aura.—M. Briand (*Presse médicale,* May 2, 1923) refers to the case of a patient who had had a skull injury and was subject to epileptic seizures. A few minutes before the seizures a very distinct nauseous odor as of decomposition or putrefaction was set free by this patient, and served as a warning to his associates, who at once adopted precautions relating to the oncoming paroxysm. The odor passed off a few minutes after the attack. The patient's clothing did not retain any of the odor. Perspiration could be ruled out as the source of the odor. There were no eructations nor borborygmi; consequently, the odor did not seem to come from the stomach. By exclusion, the conclusion was reached that it was exhaled from the lungs. The question of odors set free from the human body is still very obscure.

Contributions to the Clinical Appearance and Pathology of Tetanus.—Herb. Elias and Stef. Weiss (*Wiener Archiv für Innere Medizin,* April 5, 1922) proved that the increase of the inorganic and total phosphorus in the serum of cases of tetanus did occur. The inorganic as well as the total phosphorus is not reduced to normal with the onset of the latency of tetanus, but on the contrary it even increases for some unknown reason during this time, sometimes quite considerably.

Diagnosis and Treatment of Tetany.—Stewart R. Roberts (*Southern Medical Journal,* August, 1923) says that if the general therapeutic indications in the treatment of tetany are once understood, the details fashion themselves very easily.

1. To stop the convulsions and spasms, relieve the laryngospasm and lessen the irritability of the nervous system.

a. Morphine is given hypodermically in doses from one sixtieth to one fourth grain, and chloral hydrate from two to twenty grains by mouth or rectum. When the convulsions are extreme, chloroform inhalations may be necessary. Repeated hot baths are extremely soothing. In one case I felt that two lumbar punctures aided in relieving the severe and repeated convulsions.

b. The laryngospasm requires active treatment. Warm baths, castor oil, high warm enemas, chloral and hot stupes to the neck are advisable. When the child is in apnea, cyanotic, and dissolution threatened, dashing cold water on the face and body or quickly elevating the feet and lowering the head may help. Intubation apparently is useless.

c. Since Marriott and Howland have shown the fall in the calcium content in the blood serum in tetany, a chemical reason on a more permanent basis is proved for the therapeutic use of calcium to relieve the convulsions and spasms. Calcium chloride is the drug of choice given in doses of five to fifteen grains four to six times daily. It requires from one to two days before it influences the disease, and should be continued for a long time, say three to six weeks, inasmuch as it is eliminated very rapidly. In emergency, it may be given intravenously in normal salt solution in ten to twenty-five per cent. strength.

2. During the acute attack, cow's milk should be withdrawn or greatly diminished and cereals and gruels substituted. In older children and adults the fresh vitamine containing vegetables are in order. A well balanced diet is indicated when possible.

3. Hygienic measures are particularly important In one case I was impressed with the improvemen when the child was given abundant fresh air and sunshine.

4. When tetany is associated with another disease which bears to it a causal relationship, treatment of the primary disease is essential.

a. Tetany associated with rickets emphasizes the treatment of rickets and the administration of cod-liver oil and small doses of phosphorus. These can be given in one prescription. In children ten drops of the oil in each dose is often sufficient.

b. Tetany associated with pregnancy usually continues until the pregnancy is interrupted or terminated naturally. Lactation tetany demands the cessation of nursing if large and continuous doses of calcium are unavailing.

c. Gastric tetany associated with pathology of the stomach, duodenum or colon usually demands surgical and mechanical aid. The mortality here is high on account of age and the danger of operation. The prognosis is grave if the stenosis is cancerous in origin, hopeful if benign.

d. Tetany associated with and following operation upon the thyroid gland intimate the necessity for the use of the parathyroid hormone in the form of the tablet. The organotherapy seems useless in tetany from other causes. Parathyroid transplants and grafts may be considered in such rare cases.

Hypselophony. A New Method of Examination.—Ante Grgurina (*Wiener klinische Wochenschrift,* August 3 and 10, 1922) reports a new method of examination, consisting of the production of different kinds of characteristic sounds. The following three phenomena are the most important 1. The slapping phenomenon—slapping with the volar surface of the finger in short and rapid blows simultaneous auscultation shows a distinct metallic-sounding noise in the presence of a pleural exudate 2. The blow phenomenon—short blows with the volar surface of one or more fingers; a metallic, high-sounding, sawing noise is heard on the back in the presence of the pleural exudate. Although the slapping phenomenon is positive also in extrapulmonary tumors, the blow phenomenon is negative in such conditions. 3. The pocket alarm clock phenomenon—the edge of a pocket alarm clock is placed on the border of an area of extrapulmonary dullness and a positive sign shows a metallic, rattling noise on the back.

Treatment of Epilepsy.—John McCartney (*British Medical Journal,* January 6, 1923) treated eighteen patients by the following method: The patients were put on potassium bromide ten grains, borax purificans five grains, and Fowler's solution two minims, three times a day. This dosage was gradually increased and the best results were obtained with potassium bromide fifteen grains, borax purificans 7.5 grains and Fowler's solution two minims, three times daily. A laxative was also given at bedtime.

Continuous treatment given along these lines showed no deleterious effect on the health of the patients, producing no gastric or skin disturbances and even produced a general improvement in their physical condition.

Has Adrenin Any Physiological Value in the Organism?

An Answer to the Destructive Criticism by Some Modern Physiologists of the Physiopathology of the Suprarenal Glands

By NICOLA PENDE, M.D.,
Messina, Italy,
Professor of Clinical Medicine in the Royal University of Messina, Italy.

From 1902 to 1909, when my monograph on the pathology of the suprarenal apparatus and of the parasympathetic organs was published, (1) I made a series of researches on the experimental physiopathology of the suprarenal glands at the Institute of General Pathology of Rome. Since that time this important question has been investigated by me from the clinical point of view. I trust that my twenty years of work will justify my temerity in opposing with countercriticism, based upon facts and observations, for the most part personal, certain hasty and revolutionary ideas given forth by several well known physiologists in the past five years. These authors, Gley, Hoskins, Stewart, Swale Vincent, have promulgated ideas which may be summed up in this statement: Adrenin has no physiological importance in the organism, it is probably a product of waste or excretion (Gley), or a relic of a remote philogenetic epoch (Stewart). They also assert that the syndromes of adrenal insufficiency are purely inventions of clinicians of uncurbed imagination (Stewart), inasmuch as all the suprarenal functions devolve upon the cortical substance.

The most stubborn and bluntest critic of all is the Cleveland physiologist Stewart: it is therefore by a calm, dispassionate analysis of his conclusion (2) that I shall refute them one by one, in order that I may be able to affirm that not one of them resists the test of clinical and experimental facts, based upon accurate observation and interpreted with common sense.

STEWART'S AFFIRMATIONS.

1. The syndrome of suprarenal insufficiency shows nothing definite or characteristic. The anorexia, the muscular asthenia, the hypopyrexia which precedes by twenty-four to forty-eight hours the death of the totally suprarenalectomized animal, are not pathognomonic, except possibly the muscular weakness which progresses more rapidly than in animals dying from other experimental conditions. Further, the rapid emaciation, the grave loss of weight (which according to Stewart was observed by Elliott in 1914 although others, including myself, had emphasized it many years before) is due largely to the anorexia of the animals operated upon.

Whoever has attempted to bring about a slow syndrome of adrenal insufficiency experimentally, must have been struck by the constancy and clearness of a series of symptoms which develop always in the same order, are always the same and differ from the symptoms which are observed in animals which have been thyroidectomized or hypophysiectomized. These are analogous experimental syndromes to, but not identical with, the syndrome of suprarenalectomy. In certain cases of suprarenal insufficiency artificially produced and slow in progress, one may observe an intermittency of certain of the most characteristic symptoms, such as muscular asthenia, especially in the posterior extremities, their temporary latency, and their reappearance and aggravation with the progress of suprarenal destruction. I have brought about this syndrome of slow suprarenal insufficiency in which at first the right suprarenal gland was removed and half of it grafted into the omentum of the same animal. Later, after fifteen to thirty days, the left suprarenal was removed. In the cases where the graft was successful I was able to keep the animal alive for a month after the second operation, while animals did not live over ten days when the two suprarenals were removed in three stages.

Now in those animals in which the only functionating suprarenal tissue was that of the graft of one half of one gland, the experimental conditions were similar to those seen in man with an advanced functional or anatomical alteration in both suprarenals, which however is still compatible with life. As in

Copyright, 1923, by A. R. Elliott Publishing Company.

these cases occasionally a minute fragment of suprarenal tissue suffices to render almost entirely latent the clinical syndrome (this sometimes consisting merely of a mortal paroxysm more or less unexpected and sudden), so I have noted in several kittens operated upon by the above method, a latency or intermittency of some symptoms for several days, and then rapid unexpected death of the animal with the usual symptoms of total suprarenalectomy. Only one symptom was never lacking in our experiments, even with long prolongation of life and slow development of the syndrome. This symptom was the progressive emaciation, on which, however it did not seem to me depended directly the other characteristic and constant signs of acute or chronic experimental hypoadrenia.

These signs are hypopyrexia, muscular weakness more marked in the posterior limbs, somnolence, pallor of the visible mucous membranes and ischemia of the skin. Neither do I believe that such emaciation can be attributed to anorexia. Stewart's first affirmation is not therefore sustainable.

2. "In the experimental suprarenal syndrome there is no correspondence between the gravity of the symptoms and the quantity of suprarenal tissue removed."

This objection is of no value: with all endocrine glands, frequently a fragment of gland suffices to keep the syndrome or insufficiency latent. One of the cardinal principles of endocrinology which I set forth in my treatise on endocrinology (2) is that "the clinical symptoms do not correspond with the pathological anatomy of the ductless glands."

In man, as in animals, there is no definite correspondence between the extent of the lesions and the gravity of the symptoms, until the lesion reaches a stage where the organism can no longer utilize its complicated mechanisms of functional compensation. Then the syndrome bursts forth and progresses more or less rapidly. Finally, as I have emphasized above, it is not true that a certain gradation of hypoadrenal symptoms cannot be experimentally produced. Even in puppies and kittens deprived of one adrenal gland, I have shown, as did Vassale, Silvestri and Tosatti and Ferreira de Mira, the existence of a latent or partial suprarenal insufficiency which manifested itself on the addition of an aggravating factor such as an infection of the operation wound, or pregnancy, exactly as is seen in animals which have been partially thyroidectomized or parathyroidectomized.

Therefore, Stewart's second statement is not justified.

3. "The essential alterations produced by suprarenalectomy have to do with metabolism, but there is nothing definitely known about them."

On the contrary, the researches of the Italian authors Segale and Mariani, and those of Noel Paton and of Gradinescu, confirmed recently by the American writers, demonstrate the slowing of the basal metabolism and of protein digestion in suprarenalectomized animals. Further, they have shown the important regulating rôle played by adrenalin in protein metabolism, in the production of creatinin (Roux and Taillandier) in the renal elimination of urea and creatinin (Marshall and Davis.) To this same adrenalin Stewart denies any action whatever. To the above may be added the undeniable part played by the suprarenal cortex in the metabolism of lipoids.

4. "The arterial hypotension and the rapid muscular asthenia of suprarenalectomized animals are not sufficiently specific to be referred to the absence of the suprarenals." Here Stewart, who has already admitted a certain specificity in the muscular asthenia, forgets this and also that in patients with Addison's disease, as has been recently stated by Marañon in his criticism of Gley, arterial hypotension and muscular asthenia are conspicuous and early symptoms.

Even if they are not constant, their significance is not lessened for the reasons given in No. 2. They are not antemortem symptoms and are never found in any other morbid state as dominant, persistent and characteristic as in lesions of the adrenals.

5. "The hypoglycemia found in suprarenalectomized animals is of no value, it is found here in animals which are moribund." In this regard, experimental researches are contradictory: hypoglycemia has been found by some and not by others in adrenalectomized animals again, it has been found in some animals and not in others. The question has not been settled, as Stewart believes. This symptom, when it exists, is not only found in dying animals as demonstrated by the clinical observation of the frequent existence of hypoglycemia in patients affected with Addison's disease. Marañon, Carrasco and Soler are among the more recent observers in this regard.

6. "The emaciation observed by Abelous and Langlois in guineapigs partially adrenalectomized is not easy of interpretation; it may be due to operative trauma."

Here Stewart forgets that Elliot, whom he also quotes, and all other experimenters have noted the early appearance and gradual development of this fundamental symptom. (See also my experiments quoted in No. 1). Also in the ligation of the suprarenal veins recently performed by Hartman and Blatz in America, a visible emaciation was found in some animals.

This emaciation is never lacking in Addisonian patients. The hypothesis of Stewart that the emaciation depends upon the trauma of operation is without foundation.

7. "Whipple and Christman have demonstrated that in dogs with three fourths of their suprarenal tissue removed, the elimination of phenoltetrachlorphthalein in the bile is diminished; it increases if the remnant of suprarenal tissue hypertrophies.

Stewart remarks that this is truly suggestive but that pancreatic deficiency brings about the same phenomenon."

But what does that signify? Does it take away the value of experiments which demonstrate once more the part played by the suprarenal glands in metabolism?

8. Hoskins in 1915 showed that in dogs surviving the removal of five tenths to six tenths of their suprarenal tissue, the vasomotor reaction to nicotine is diminished and he concluded that partial suprarenal insufficiency diminishes sympathetic excitabil-

ity. What has Stewart to bring forward against these experiments?

9. Stewart and Rogoff, as also Gley and Quinquand, affirm that the hyperglycemia of bulbar puncture, from ether anesthesia, or from asphyxia, is seen equally when the suprarenals have been extirpated, contrary to what had been believed from the experiments of others. This would deny to adrenalin any influence on the hyperglycemia of bulbar stimulation.

But in 1920 Negrin and Hernandez Guerra confirmed experimentally the relationship between bulbar glycosuria and hypersecretion of adrenalin. This does not preclude the possibility that the bulb may act directly on the liver to bring about a hyperglycemia; the two mechanisms producing this, namely the direct neurogenic and the secondary neurohormonic or sympatheticoadrenal, do not exclude one another.

10. "There is no difference in the resistance to fatigue in normal animals and those with grave insufficiency of adrenal tissue."

This affirmation of Stewart, in disagreement with previous physiologic experiments and clinical findings, is experimentally unjustified and premature in view of the excellent recent researches of Hartman in America, according to which there exists a direct parallelism between muscular work and the quantity of adrenalin which enters the blood. According to the same researches, adrenalin increases the functional capacity of the muscles and combats the toxic effects of fatigue. These researches are a striking proof of the great importance of adrenalin in muscular physiology.

Now let us examine the arguments of Stewart who attempts to deny any physiological value to the medulla and to assign to the cortex alone any functional value.

11. "If one suprarenal gland is removed from an animal and the nerves of the other gland severed, thus preventing in great part the excretion or mobilization of adrenalin from the medullary tissue into the veins, the animal does not present any disturbance; hence, says Stewart, adrenalin in the blood is of no consequence."

Before discussing the value of this experiment, I wish to draw the attention of Stewart to the fact that this experiment was first performed by me in 1903, as has been recognized in Italy, in Germany and in France (probably news of Italian experiments are late in arriving in America).

After my experiment, it was repeated in the Institute of Medical Pathology in Naples, directed by Professor Castellino, by Pellegrino in 1904, and by Giovine. I first showed that section of the splanchnic nerves and of the solar plexus slowly brought about a progressive atrophy of the medullary tissue of the suprarenals, or of the corresponding suprarenal if the section is unilateral, also an intense vasodilation of the entire gland. Immediately after the enervation, the chromaffin cells do not show demonstrable changes; this fact was reobserved by Elliott. Now I found that in kittens, by removing the right suprarenal and cutting the nerves of the left one after fifteen to thirty days, the animals did not present appreciable symptoms, other than a slight subnormal temperature.

However, I was careful not to conclude, as does Stewart, from these observations, that the abolition of the supply of adrenalin in the blood, and the neurogenic atrophy of the medulla of the remaining gland, demonstrated the uselessness of adrenalin in the organism. Stewart himself found that the entrance of adrenalin into the suprarenal veins, even when reduced to 1/100-1/1000, is abolished after section of the nerves, and we know that an infinitesimal quantity of adrenalin may suffice to keep latent the symptoms of its insufficiency. One year after my experiments, Pellegrino, by severing the nerves of one gland and removing the other at the same session, caused the death of the animal just as though both glands had been removed simultaneously.

Finally, the most important, it is impossible to deny that enervated medullary tissue may still exercise a beneficial function in the organism, because it is contrary to the concept valid for all the endocrine glands, and well shown by the grafting experiments, to admit that they function only under the influence of their secretory nerves. Actually my transplantation experiments with the suprarenals have shown me that the best results are obtained when the cortex and medulla are transplanted at the same time (here the medulla is free from nerve control).

We may add that even when the suprarenal medulla is atrophied or paralyzed, as to its excretion of adrenalin into the blood, there remain many chromaffin cells scattered through the whole sympathetic which pours adrenalin into the circulation. Stewart and Swale Vincent refuse this objection because they believe that the section of the abdominal splanchnics and the removal of both suprarenals will produce death equally surely in spite of the existence of the abdominal paraganglia; hence the latter and their adrenalin are of no value just as are the medullæ of the glands.

To the first argument we may reply that, even when the abdominal paraganglia are enervated, there remain many nests of chromaffin cells in the thoracicocervical sympathetic which are not influenced by the cutting of the splanchnics. To the second argument we may answer that the fact that the presence of the paraganglia does not suffice to preserve from death the animal deprived of both suprarenals may be interpreted, as was done by me in 1909, to mean that only the physiological unity of the cortex and medulla is capable of supplying the exigencies of life.

12. "The ligation of the suprarenal veins does not determine hypotension, nor does the pressure rise after the release of the veins (Young and Lehmann's experiments, contrary to the results of Strehl and Weiss); therefore, adrenalin, whether it enters the suprarenal veins or not, does not modify the arterial pressure."

Apparently this is an impressive fact; however it is sufficient to consider that recent accurate experiments by Hartmann and Blatz in ligating the suprarenal veins, with a histologic study of the glands, demonstrate that even with the veins ligated adrenalin may continue to enter the circulation by infiltrating through the cortex, whence it may reach the general circulation by the anastomosis of the suprarenal veins with the renal veins. Further, it is known that in other endocrine glands, as the thyroid, the ligation of the veins (Mattioli) does not abolish the entrance of the secretion into the blood stream nor the function of the gland. Again, if the experiment of ligation of the veins demonstrates the uselessness of the adrenalin in the circulation, why do not Stewart and Vincent conclude that the cortical secretion is valueless if it is prevented from entering the circulation by the ligation of the veins?

Hartmann and Blatz have in fact observed phenomena of hyposecretion of cortical lipoids after ligation of the veins.

This experiment, for my part, has no demonstrable value either for or against the value of adrenalin, since the observations on the animals were carried out for a limited time, and we know that even when both suprarenals are removed a certain period must elapse, up to twenty-four to forty-eight hours, before the appearance of the first hypoadrenal symptoms.

13. "According to Stewart and Rogoff (Cannon to the contrary) the acceleration of the enervated heart, whether from psychic stimuli or stimuli of sensory nerves, is not due to the adrenalin supply; this adrenalin has nothing to do with emotional reflexes."

Recently the researches of Cannon, Undill and Griffith have shown, on the contrary, that it is really the adrenalin which determines acceleration of the heart.

The socalled emergency theory of Cannon has been recently well demonstrated by the above mentioned researches of Hartmann with regard to the increase of adrenalin in the circulation during muscular exertion.

Again, the researches of V. Anrep in great part confirmed by Vincent and Pearlman, demonstrate the importance of the presence of adrenalin in the blood in the determination of the typical curve of splanchnic stimulation observed by Elliott (which Gley and Quinquand had denied).

14. "When one suprarenal is removed the other hypertrophies and the hypertrophy involves only the cortex; this is a sign that it is the more vital part."

Based upon my own observations, which agree with those of Lucibelli, Simmonds, and Karascheff, this compensatory hypertrophy involves also the medullary portion.

15. "Only the cortex of a transplanted suprarenal gland grows."

This is in no wise true. I found in the cat, and recorded graphically, the temporary growth of the chromophile cells, which was observed by M. Christiani in the rat, and by Busch, Leonard, and Wright in the rabbit.

The possibility of securing growth in transplanted medullary tissue prompted me to attempt experimentally to separate the syndrome of insufficiency predominantly cortical from that predominantly medullary.

As I have stated I extirpated at the first sitting the right suprarenal, and at the same time ingrafted one half of it into the omentum; at a second session after fifteen to thirty days I removed the left suprarenal.

In the cases where the graft necrosed, the animal died in from two to four days with the usual syndrome of acute suprarenal privation just as after the extirpation of both glands in two stages. Three kittens survived for ten, fifteen and thirty days respectively; in the one which lived ten days, the day after the removal of the left gland the symptoms of hypoadrenia were manifested and progressed steadily until death. Examination of the grafted gland showed absence of chromaffin cells, and the presence of several islands of well preserved cortical tissue.

In the animal which survived fifteen days an interesting fact was noted, namely, that for fifteen days there was complete absence of all symptoms of adrenal insufficiency, except for a slight degree of emaciation. On the fifteenth day the animal unexpectedly was seen to fall back on his hind limbs, unable to move; this was followed by somnolence, hypopyrexia and death. In this case, examination of the graft showed complete sclerosis of the cortex, while almost the whole medulla remained in an atrophied state.

The third kitten lived a month after the extirpation of the second gland and showed, the day after the operation, falling of the hair, constipation, and pallor of the mucosae. These symptoms disappeared and returned in an intermittent form, while the emaciation progressed, although the animal was being fed sufficiently well.

On the twenty-ninth day there appeared marasmus, complete asthenia, stupor, barely perceptible arterial pulsation; on the thirtieth day death supervened after an attack of generalized convulsions.

Here examination of the graft showed many medullary cells preserved in the centre of the fragment; whereas only a few elements of the glomerular zone of the cortex were visible. While not denying the difficulty of interpreting these three experiments, and admitting their small number, nevertheless I felt justified in deducting therefrom that the longest extension of life by the preventive action of gland grafts in suprarenalectomized animals is seen when the medullary portion grows as well as the cortex.

In such a case there may be brought about a complete absence of symptoms and, analogously to what is seen in grave latent suprarenal alterations, sudden death may supervene in the animal from complete adrenal privation, when the number of growing grafted cortical cells has become absolutely insufficient.

As an hypothesis I admitted that the presence of cortical tissue is necessary in order that the medullary cells may functionate properly in the organism.

No one has succeeded in demonstrating with certainty that the presence of cortical tissue in the organism suffices to prevent the death of the animal after extirpation of the adrenals.

The experiment of section of the nerve of one gland after the extirpation of the other is not a satisfactory one for this purpose. Neither are the experiments of Wheelon, repeated by Ciaccio, (verbal communication) which were aimed at the possible destruction of the medulla of both glands without endangering life.

Here there is lacking histological demonstration of the complete destruction of the medullary cells which we know penetrate the cortical zone here and there. Furthermore, these severe operations on the medulla cannot leave intact the structure and functional integrity of the cortex.

An opinion which has many arguments in its favor is that both cortex and medulla form a physiological unit, as they are in the same organ, inasmuch as the blood, after having infiltrated the cortical zone and taken up the secretions of that zone, finally bathes the medullary cells. Again, an enormous number of nerve branches are distributed not only to the chromaffin cells but also to the cortex, especially the reticular zone which is richest in nerve endings. It is not possible either experimentally or clinically to dissociate the cortex from the medulla whose union, always more intimate in philogenetic progress, can have no other significance than a functional progression of the organ in the higher animals. Here, in my opinion, we should seek the reason for the experimental and clinical fact that the two substances, united together, cannot be so perfectly substituted that life may be preserved, by numerous chromaffin cells and accessory cortical cells scattered throughout the body.

We shall state that in spite of the fact that Swale Vincent has recently denied any physiological value to this corticomedullary union, nevertheless, Lowenthal, Bauer, Vignes and others maintain the importance of the anatomical and physiological relationship existing between these two tissues.

This is a problem which will be solved some day by biological chemistry just as it has begun to solve the mystery of the union of the prepituitary and the postpituitary.

16. Stewart's last affirmation is truly inexplicable, namely that clinicians, mostly the French and Italian, look upon suprarenal insufficiency in man as solely an insufficiency of adrenalin. Thus they base their nosographic and pathogenetic construction of hyposuprarenalism on nothing, according to Stewart, because no action of adrenalin whatever on the organism is demonstrable in the laboratory.

Firstly, it is not true that the clinicians stand upon adrenalin insufficiency; I was among the first to sustain, with Biedl, the importance of the cortex, and to apply, as I have done clinically, the theory of the physiological unity of the cortex and medulla.

Further, Sergent has defended himself against the same unjust accusation of Stewart. I have for about fifteen years advised administration of both cortex and medulla, not adrenalin alone, in suprarenal insufficiency.

As for the statement that clinicians have no right to speak of a syndrome of medullary hyposuprarenalism, because a few laboratory experts maintain that adrenalin has no action, this is a contention which has no exact basis in animal experiments, as we have shown in our critical analysis of Stewart's arguments. How can all value be denied to experiments demonstrating the participation of adrenalin in basal metabolism and muscular action?

There has been much ridicule in America of the theory of tonus, still adhered to today by clinicians, and according to which, one of the functions of adrenalin is to contribute to the maintenance of vascular tone, and the tone of the other organs innervated by the sympathetic.

One cannot deny the great significance of the law of Langley-Elliott, that adrenalin acts upon the tissues in the same manner as the stimulation of the sympathetic nerves which supply those tissues. Neither can the impressive fact be denied that in the whole series of vertebrates, and also in invertebrates, the chromaffin cells and sympathetic cells are derived from a common matrix and live and functionate together, This is an admirable proof of the intimate correlation between chemical and nervous stimuli. Nevertheless an attempt has been made (Hoskins) to deprive adrenalin of all regulating action on the sympathetic excitability, because of the observation that adrenalin, injected into animals in minimal doses, brings about hypotension instead of hypertension. This has been adduced to further the claim that adrenalin cannot act as a vasotonic hormone in the minute doses in which it enters the blood stream.

However, it has not been considered that adrenalin, even in minimal doses (Cannon, Collip) may act either as a vasoconstrictor or a vasodilator, according to the various vascular regions and the receptivity of the bloodvessels on which it acts. This is just the attribute of a substance truly capable of regulating the general vascular tone. This tone is not destined to produce general vascular constriction of all the bloodvessels of the body, but rather to provide an equal distribution of the blood in case of changed hemodynamic exigencies.

Now adrenalin, as some opponents of the theory of "tone," as Vincent, have decided, is, in certain contingencies artificially produced (the only one of the known hormones) capable of providing for the even distribution of blood in the body. Why then cannot this occur in physiological conditions?

As I have insisted for many years, that we cannot declare, as has been airily done recently, that adrenalin is a hypertensive hormone; it is hypertensive according to the needs of the organism. Does not the tonic function of the cardiovascular apparatus consist precisely in this regulating property of blood distribution?

It is difficult to understand why Hoskins, enthused over the chemical isolation of thyroxin by Kendal as the active principle of the thyroid, claims this to be the tonic *par excellence* which stimulates cells in general, and at the same time denies to adrenalin any tonic action on the sympathetic. This he denies to adrenalin, a substance which has so many analagous actions to those of thyroxin, such as stimulation of basal metabolism, independent of the presence of the thyroid; stimulation of thermogenesis in hibernating animals (Adler); stimulation of the cervical sympathetic, etc.

But, says Gley, a physiological adrenalinemia cannot be demonstrated: the search for adrenalin, which is positive in the blood of the inferior vena cava below the entrance of the suprarenal veins, is negative in the right heart.

This, however, is one of the weakest reasons for denying to adrenalin any importance as a physiologically active hormone.

In fact, if it is admitted that adrenalin enters the suprarenal veins from the medullary tissue, that its flow is regulated by the nervous system, that the hormone is recovered from the blood of the inferior vena cava, that it is capable of acting in extremely weak dilutions, then how can it be denied that it exists in the general circulation, merely because our defective technic is not successful in discovering it when it is diluted in the great mass of the blood? Might it not be said that the hormone is fixed immediately in the tissues to which it is destined?

Marfori and Marañon justly rebut the objection of Gley, saying that, even when we inject adrenalin into animals or man, examination of the blood during the period of maximum action of the hormone will not reveal its presence in the blood by the most delicate biological tests.

Can it be denied in such case that an adrenalinemia has existed or that it has been artificially produced in the animal if only for an instant?

Even if the opinion of Cannon were correct that an adrenalinemia occurs only in cases of special emergency by the call of the chromophile tissue by nervous impulses, how could this lessen the great value of adrenalin in the normal organism?

Are we able, in the case of the other glands such as the thyroid, the pituitary, to demonstrate the presence of their respective secretions in the circulating blood?

Do Gley, Vincent, Stewart and Hoskins deny the existence of the thyroid, pituitary and other hormones which physiologically enter the blood (we know not whether continuously or intermittently) to perform important functions? I shall not delay here to demonstrate how the crusade against adrenalin by famous French and American research workers is destined to fail, because it has not a single serious experimental foundation in its favor, even if we set aside, which we shall never concede, the positive contributions in favor of the importance of adrenalin, furnished by clinical experience, which Stewart holds in such disdain.

It is strange how lightly the opponents of the physiological importance of adrenalin substitute hypotheses for facts as to the importance of this substance in the organism.

Thus Gley, in saying that it is a waste product, an excretion, forgets that in admitting such to be the case, he is up against his own objection in not being able to demonstrate this product of excretion in the general circulation, as can be done with other such products.

Further, it is inexplicable how an excretion begins to be produced in the earliest months of fetal life, which has such specific stimulating properties on the sympathetic and which is so actively regulated by secretory or excretory nerves. This is truly a precious excretion which is not to be discarded as a waste product in clinical therapeutics.

Stewart thinks that adrenalin is, as it were, a relic of an ancient philogenetic era, in which the chemical stimuli were of more importance in the organism than nervous stimuli. On the contrary, we see that the chromophile tissue, especially the medullary tissue of the suprarenal, is one which develops late, and that even after birth chromophile cells continue to be formed from the sympathetogones in the suprarenals (Wiesel).

What is to be said of the hypothesis cherished by Gley and his followers (Porak for example) of the exclusive importance of the cortex in suprarenal physiology?

The French authors are not willing to abandon the antitoxic theory of the endocrine glands. This theory, which von Biedly and I have combatted for many years, and which Marañon, who was once its advocate, now admits with praiseworthy scientific honesty (3) to be unfounded, is derived from the theory of Gley and Porak as to the antitoxic function of the suprarenal cortex through the medium of its cholesterin secretion.

We shall not insist again on the frail basis of this doctrine of cortical antitoxic action, confining ourselves to the statement with Marañon (4) that on the one hand, the relation of the cholesterin of the blood with the cortical secretion is yet to be demonstrated, while, on the other hand, there is no parallelism between the cortical cholesterin secretion, the degree of cholesterinemia, and the antitoxic and antibacterial power of the blood. It is remarkable that the same criticism of Gley of the theory of medullary function has not been applied by the great Parisian physiologist to his hypothesis of the cortical antitoxic function as being the exclusive function of the whole gland.

It is better, as to the function of the suprarenal cortex, to maintain still a prudent reserve, as I did in my monograph of 1909, and to admit simply a relationship not yet precisely defined, between the cortical secretion and lipoid metabolism, and with the elaboration of pigmentolipoid combinations. The latter function, as Laignel Lavastine has shown, is controlled by the nervous system through the solar plexus. Further, the cortex must have a great influence on the trophism of tissues which are highly differentiated and rich in such pigmentolipoid combinations, such as nervous tissue, genital gland tissue, and the Malpighian mucous layer.

It is of interest to touch upon one last point; this is the relationship of certain attenuated forms of adrenal insufficiency, which lie on the borderline between physiology and pathology, and certain individual constitutions and temperaments. This relationship has been especially studied in Italy by Castellino and his pupils, by myself, and has found support in Germany (Brugsch, I. Bauer, Wiesel and others) as well as in Spain, France and elsewhere.

Such hyposuprarenal constitutions, according to Stewart and Hoskins, are fantastic constructions, for the sole reason that they cannot be experimentally reproduced!

This would mean that clinical medicine (whose latest and most recent task is exactly that of defining borderline states between health and disease, temperamental morbid forms, or subpathological or premorbid states) should renounce this mission, which we consider one of the highest of modern medicine, simply because the laboratory is still unable to solve the problems of morbid constitutions and temperaments.

Fortunately there are, among the most keen experimenters, level heads who feel that even in precise laboratory tests they cannot do without the light that comes from the patient. Von Biedl, in the last edition of his well known treatise on endocrinology (now on the press), devotes hundreds of pages to the examination of the individual constitution, in its relationship with the physiology and pathology of the internal secretions, thus giving all his authoritative support to the trend which we have followed for many years in clinical endocrinology.

Therefore, in this field, the criticism of the American physiologists, who as Hoskins recognizes, have imperfectly understood the constitutional tendency of modern medicine, is shown to be premature, risky, and not guided by sane clearness of thought and scientific method, which alone can prevent even the most brilliant scientist from falling into gross errors of common sense. We can then understand how an investigator of the calibre of Stewart, in his attempt to destroy the value of clinical facts, with which he has little familiarity, and to accuse the clinicians of inventing the syndromes of suprarenal insufficiency, cites a case of Claude and Gougerot in which during life there existed asthenia, melanodermia, arterial hypertension of 90 m.m. In this case the adrenals were atrophied, reduced to half their normal size, although apparently histologically unchanged; this patient was tuberculous.

Now, says Stewart, in animal experiments it is sufficient to leave a fragment of suprarenal tissue in order to prevent the appearance of the symptoms of Claude and Gougerot's patient with suprarenal atrophy.

Whoever has had any anatomical and clinical experience with Addison's disease, knows that simple or sclerotic atrophy is not a rare lesion as has been established by Bittorf. And do we not find thyroid atrophy as an underlying pathogenetic factor in many cases of myxedema; do we not find hypoplasia or atrophy of the pituitary as an anatomic condition in some cases of hypopituitarism?

And is not the same true for the relationship of testicular atrophy to certain cases of eunochoidism?

Another case which Stewart cites as an example of the weakness of the clinicians in the diagnosis of suprarenal insufficiency is that of Boyd. This was a soldier who died suddenly although apparently healthy and without Addisonian symptoms, and yet at autopsy extensive tuberculous lesions of the lungs were found! Section showed both adrenals transformed into a caseous substance; in the left one there was a streak of cortical substance preserved, two millimeters thick, and an absence of medullary cells.

Stewart reproves Boyd with having diagnosed postmortem and acute suprarenal insufficiency. As a matter of fact, who does not know that such sudden death in patients with latent grave suprarenal lesions is very common? We have experimentally reproduced this form of latent suprarenal insufficiency, with sudden death (see above). But, according to Stewart, this case could not be diagnosed as acute suprarenal insufficiency, because the symptoms of insufficiency (if there are any characteristic ones, he says) were lacking in life; and the case shows that merely a tiny portion of cortex suffices to maintain a state of apparent health and vigor.

Why then did the patient die? It could be supposed that sudden death occurred when the last medullary cells ceased to function and to lend their aid to the cortical cells, which are incapable themselves alone of sustaining life (see above).

We shall conclude with the plea that, even in endocrinology, laboratory experts convince themselves at last of the necessity of observing and experimenting upon the human patient, from whom have been obtained almost all the most exact knowledge in the field of the physiology of the internal secretions.

As Barker and Sajous in America have rightly noted, it is only by the collaboration of all the branches of biology and medicine, and by the balanced synthesis of all their contributions, that advances can be made in the study of endocrinology.

Following the tradition of the Italian medical schools, according to which one cannot conceive of a clinician who is not also a physiologist and experimental pathologist, we shall continue to have faith in the principle of the great Roman clinician, Guido Baccelli, that "the best laboratory of human experimental physiology is the sick man."

A Case of Hypopituitarism with Epilepsy*

By HYMAN TUCKER, M.D.
Elgin, Illinois.

In the study of endocrine problems, the rapid success made in the last few years, especially with regard to differentiating certain syndromes, and the varying success in their treatment by either supplying the deficient gland in the case of hypofunction or attempting to antagonize an overactive member of the group, have, it seems to me, been a great factor in interesting the medical profession as a whole in endocrinology, and even converting some confirmed sceptics. Particularly in the field of psychiatry, in the socalled functional disorders, where no definite organic changes have been consistently made out, this at least promises to open a new mode of attack. The danger, obviously, is that we become overenthusiastic and feel that in every unexplainable abnormality or difficult complex, it is simply a matter of *"cherchez la femme"* in the guise of the ductless system. Our knowledge of any but the thyroid and possibly the pituitary glands is extremely limited and lies rather in the field of speculation. The majority of the endocrine disorders appears to be of a pluriglandular nature, one of the glands principally leading the way and soon followed, because of the close interrelationship, by dysfunction of one or more of its fellows.

There are a certain number of cases, however, in which the signs of a dysfunction of one of the glands are so pronounced as to almost completely overshadow the clinical picture. Such a case I have to present, one of deficient secretion of the pituitary gland associated with epilepsy.

---

*The above case was presented before the Brooklyn Neurological Society on February 15, 1922.

Cushing, who perhaps knows more about the pituitary, and has done more original work on it in the last few years than any single worker, gives six reasons why pituitary insufficiency is related to epilepsy.

1. Horseley of London noted increased excitability of the motor cortex of hypophysectomized dogs.
2. Epileptiform convulsions were frequently seen in animals, which survived for long periods of time after partial removal of the pituitary.

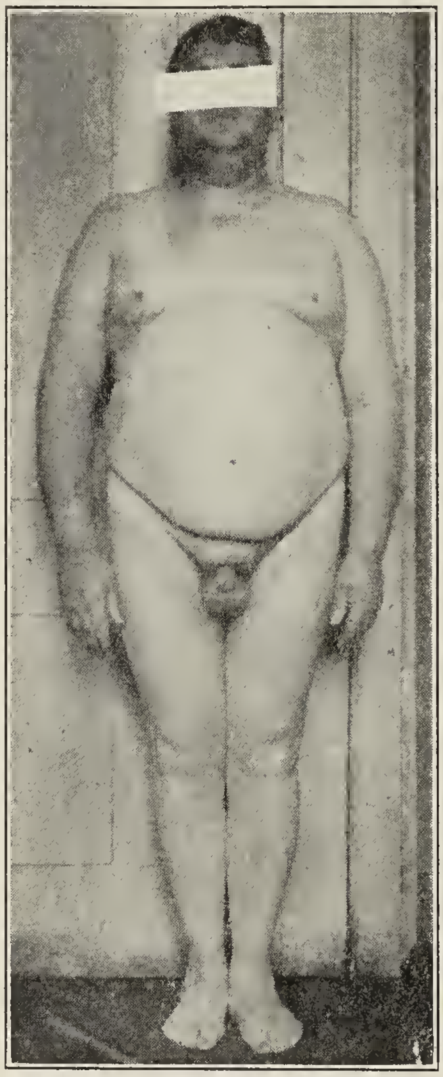

Fig. 1.—Patient on admittance. Note feminine distribution of fat.

3. Epilepsy is a frequent accompaniment of clinical conditions in which insufficiency of the pituitary is manifest.
4. The pituitary may be damaged from a bursting fracture of the skull, where epilepsy follows trauma.
5. It is believed that the posterior lobe secretion enters the cerebrospinal fluid bathing the cortex with a substance essential to the functional stability of the cortical cells.
6. In many epileptics with apparently genuine seizures, presenting hypopituitary symptoms, pituitary extract has modified or decreased the number of seizures.

The patient in question has an interesting history, having had residence at Craig Colony and the Rochester State Hospital before admission.

Case.—He was thirty-six years old; single, a laborer; was born in the United States, and had a common school education, reaching the first primary grade. His father died at fifty-one years of age, of socalled rheumatism. He is said to have been alcoholic, a steady drinker but seldom intoxicated. He was also rather stout. His mother was alive and small in stature. The only other member of the family, his sister, showed no tendency to obesity. The patient was said to have been born at full term, a normal delivery, but was puny. There was no difficulty or delay in dentition, walking or talking. He had diphtheria at the age of six, measles at eight and typhoid fever at twelve, from which time he began to take on in weight. When nineteen years of age he was struck on the head by an iron bucket, receiving a lacerated scalp, which was sutured. The first seizure is said to have occurred nearly a year subsequent to this head injury. Following that they came about every two or three weeks. The patient stated that he had severe headaches immediately before and following the seizures. He also had an aura in the shape of dark clouds before his eyes, became very angry, wanted to tear his clothes and break things. The attacks were accompanied by hysteroid symptoms. During the seizures consciousness was lost and there was amnesia for the period.

He had been employed in various shops as an errand boy. At one time he was arrested for attacking his mother. He had been examined and treated at the Long Island College Hospital, St. Peter's Hospital and Blackwell's Island. On August 13, 1908, he was admitted to the Craig Colony at Sonyea. Physically, there he was described as well nourished, obese, of a feminine type; height five feet three and a half inches and weighed 170 lbs.

Following his admission he was given work in the kitchen. His life there was uneventful until December, 1918, when after some seizures he became confused, ran about, pounded on the floor and walls and broke some windows. Allowed to go to the village some time later, he became intoxicated and used obscene language. Two months later, in April, 1909, he attempted suicide by throwing himself into a pond, but was rescued. During the next few months he had these semihysterical attacks of the same nature, when he would run around the ward, shouting and striking his head against the wall. At times he was violent and quarrelsome. In March, 1912, following a seizure, he jumped through a second story window to the roof of a veranda and then to the ground, clad only in a nightshirt. He disappeared in the darkness and later was found near the district school, about a mile distant, furiously ringing the bell in the belfry and shouting that he was calling the people to the services. He then was rather well behaved until November, 1913, on the evening of which he followed a female employee and attempted to criminally assault her, but was frightened away by the approach of some attendants. A few hours later he was found lying on the railroad tracks in an attempt at suicide. There was some doubt about this, because he was shouting at the top of his voice and attracted the attention of two attendants who were looking for him.

In February, 1914, he passed the Simon-Binet test at a level of ten years, his actual age being twenty-eight. He later confessed to burning a barn the previous August, saying that he had read about the blackhand doing the same thing. That same month he was indicted for assault and was committed to the Rochester State Hospital on February 25, 1914.

At the Rochester State Hospital he was described as simple and childish with episodes of excitement. On June 7, 1921, he escaped and went to the home of his sister, where he had no convulsions until December 9, 1921, and in the excitement following that he was taken to the observation ward.

He was described as always somewhat troublesome and complaining. He was admitted to the Brooklyn State Hospital on December 13, 1921. He had never caused any trouble, had been pleasant and

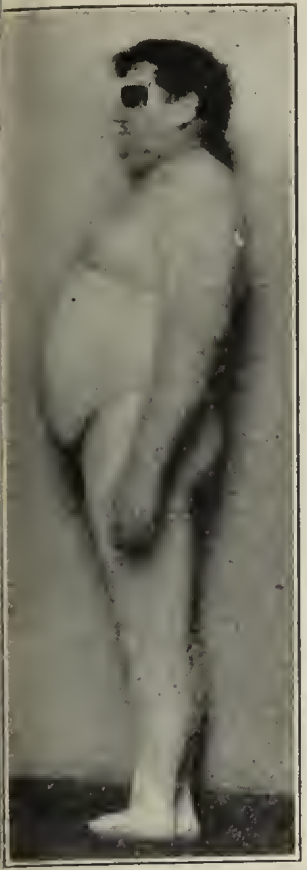

FIG. 2.—Side view of patient.

agreeable but simple and superficial; did quite a bit of work in the wards and had no attack of either *grand* or *petit mal.* Of the epileptic character he has shown some emotional poverty, but no egocentricity or supersensitiveness. A Binet-Simon test showed him to be nine and a half years old mentally. His actual age was thirty-six.

PHYSICAL EXAMINATION.

He was five feet and four inches in height; weighed 230 pounds, very obese with a feminine figure. The fat was distributed, especially at the breasts, shoulders and abdomen. His trunk length was eighteen inches; leg length thirty-three inches, and arm span sixty-eight inches.

The circumference of the head was twenty-three inches, length being eight and a half and width seven inches, making it brachycephalic in type. Its volume was estimated at 1552 c. c. He had an infantile face, normal eyes with an interpupillary distance of two and five eighths inches. Eye movements were normal. There was no diminution in any field. Ophthalmoscopic examination revealed a general lack of nutrition, a thinned out retina and a pale optic nerve, suggesting a beginning atrophy. The glabella, supraorbital ridges and malar eminences were not prominent. The nose was small and straight. Right ear showed a Darwinian tubercle; left ear negative. Both upper and lower jaws were recessive. The palate was low, arched and showed no torus. The teeth were poorly preserved and there was some spacing between the centrals and laterals on both sides in the upper jaw. The right upper 2nd bicuspid and upper 3rd molar were missing. There was no clinical evidence that they were ever present. The lower teeth were crowded. The gums showed a moderate pyorrhea. The neck was short and thick, its circumference being seventeen inches. The thyroid was not palpable.

His spinal column showed a kyphosis at the cervicodorsal region and a lordosis at the lumbosacral region. The thorax was short and wide, having an obtuse subcostal angle. The circumference at the nipple line was forty-six inches on deep inspiration and forty-four inches after deep expiration. The lungs were negative. The abdomen was pendulous and showed striæ. At his waist line he measured forty-five inches. The viscera were negative. The pelvis showed a marked resemblance to the feminine type. The width at the crests was fourteen inches, and at the trochanters sixteen inches. The legs and arms were well rounded and of the feminine type. His hands were rather large, being nine inches around, long and broad with tapering fingers. Genu valgum was present. The feet were narrow, long and toes rather square. Both arches were flat. Muscular development was fair but the tone poor; he fatigued easily. No hyperextensibility, atrophy or paralysis was evident.

His skin was dry, warm and smooth, except on the back of his hands; here it was rough, showed a wrinkling with deep cutaneous furrows surrounding each digit. He perspired moderately in the axillæ, the perineum and on the forehead. His face was ruddy and flushed at times. There was a marked dermatographia. There was some slight pigmentation on the upper extremities. The nails were smooth and brittle. The hair distribution was of fine texture, showing a good growth on the head, but rather sparse over the outer third of the eyebrows. He shaved twice weekly. Axillary hair was scanty and his arms, legs and chest showed a thin distribution. Over the pubis there was a tendency towards the female arrangement.

The cardiovascular system showed nothing striking. Heart tones were of fair quality, clear. No cardiac enlargement or murmurs, the pulmonic second louder than the aortic second. Pulse varied between sixty and eighty, normal reaction to exercise, volume medium, no cyanosis. Blood pressure varied between 140 and 170 systolic—eighty and 110 diastolic. The oculocardiac reflex was normal.

The tonsils were small, some adenoid tissue was present. The thymus was negative to percussion. There was no other glandular enlargement. The sexual organs appeared small, but the testicles were about normal in size and consistency. The scrotum and penis were small. The libido was diminished, but present and he had an occasional erection. The prostate was definitely smaller than normal. The neurological examination was entirely negative. He spoke in a monotone with a childish accent, his voice being rather high pitched. He had frontal headaches with some dizziness and an occasional vomiting spell in the morning. His appetite was increased, especially for meat and sweets. He became drowsy in the afternoon and sometimes fell asleep. He had a nycturia but no polyuria.

One one hundredth gr. of atropine sulphate caused a slight drying of the throat, but no change in his pupils or pulse. After an injection of one twelfth gr. of pilocarpine hydrochloride he complained of increased salivation and some sweating around the eyebrows. There was no change in pulse.

The Goetsch test:—Injection of seven and a half minims of 1:1000 solution of adrenalin caused no change in his pulse, respiration or blood pressure for an hour. Objectively, he merely showed slight tremors of the fingers and tongue. Did not feel nervous in the least.

LABORATORY FINDINGS.

Two daily specimens of urine were absolutely negative with specific gravities of 1.020 and 1.024. Three twenty-four hour specimens, however, showed from one and three fourths to two per cent. sugar. Amounts voided varied from 1110 to 1290 c. c. and specific gravities from 1.032 to 1.036. No albumen, diacetic acid or acetone were present, but there were a few pus cells and an occasional hyaline cast.

In the two hour specimens the specific gravities varied from 1.026 to 1.032. 500 c. c. were voided during the day and this amount contained twenty-six grams of urea.

Phenolphthalein test was 35 per cent. for first hour and 20 per cent. for the second hour.

Two determinations for blood sugar were done. One was 90 milligrams per 100 c. c. of blood. The other was 95 per 100 c. c. Red blood cells 4,800,000 per c. mm., hemoglobin 85 per cent., white blood cells 7,200. Differential: Polymorphonuclear 62 per cent., small lymphocytes 24 per cent., large lymphocytes 11 per cent., basophiles 1 per cent. and transitionals 2 per cent.

The blood Wassermann was negative. No sugar tolerance test was done because of the glycosuria. A blood sugar after ingestion of glucose was not done due to lack of time.

X ray of hands shows increase of soft parts and union of epiphyses. The sella turcica appeared a bit irregular and flattened from above downwards. The greatest anteroposterior distance was 10 m. m. The sella was 5 m. m. deep and there is no space between the clinoids, they being almost in apposition. No evidence was found of an old fracture.

TREATMENT AND COURSE.

He had been getting anterior pituitary extract, two gr. t. i. d. for almost a month. The only improvement shown was his own statement that he was not quite so dizzy at times. No other change had been noted. His temperature ranged from 98.2° to 99°.

Owing to the condition being of such long standing, no great hopes were entertained from organotherapy.

SUMMARY.

The important points that present themselves are:

1. That he began to take on weight after his recovery from typhoid fever.
2. That he received a definite trauma to the head and a year later developed epileptiform convulsions.
3. There has always been some question as to his attacks being genuine epileptic seizures.
4. That he had had no seizures while at the Brooklyn State Hospital.
5. That he has a hypertension and a glycosuria which complicate matters.

To review the characteristic syndrome of hypofunction of the pituitary, we have a relatively short, very obese person with a decidedly feminine figure, a sparse distribution of hair, tapering fingers, underdeveloped genitals, a high pitched voice, who becomes drowsy at times, has a great fondness for sweets, and gives evidence of what appears to be a small sella turcica.

As regards his hypertension, we have not been able to satisfactorily explain it. The possibilities are arteriosclerosis, cardiorenal disease, a concomitant thyroid or adrenal hyperfunction or some toxic condition; none have any evidence to support them.

The glycosuria is evidently not of true diabetic origin; neither is it alimentary; nor can it be explained by disease of the kidney, thyroid or adrenals. There is a possibility of renal diabetes, with lowered threshold for sugar. It is probable, however, that both conditions have the same etiological factor, which as yet we have not determined.

Elgin State Hospital.

---

[1] Since that time, the patient has had one seizure of a pseudo-epileptic nature with a decidedly milder reaction.

Preadolescent Gigantism with Precocious Puberty in Brothers*

By NORMAN M. MACNEILL, M.D.,
Philadelphia,
Instructor in Pediatrics, Jefferson Medical College.

History and mythology are filled with accounts of the exploits and accomplishments of fabulous monsters called giants. Many of these accounts are founded on fable, though it is not unlikely that a few represent exaggerations of actual accomplishments by persons whose stature or prowess was great in contrast to that of their contemporaries. The ancients believed that the human race had degenerated from its primeval ancestors who were thought to have been gigantic, and it was not until the nineteenth century, when scientists declared that the supposed remains of human giants were in reality the bones of mastodons and other large animals, that the belief in a vanished race of physical supermen was relinquished. Even the great naturalist Buffon fell into the error of considering certain bones of an elephant those of a human giant. Among the recorded giants of history is the Arabian mentioned by Pliny whose height was nine and a half feet and two others who were over ten feet.

Winkelmier the Austrian giant measured eight feet ten inches. A Scottish giant in the service of Frederick William I of Prussia, measured eight feet three inches. Cujanus, a Swedish giant exhibited in London in 1872, was about nine feet. Capt. Bates and his wife, Anna Swan, natives respectively of Kentucky and Nova Scotia, were both over eight feet in height.

Skeletons in the museums of Trinity College, Dublin, and the College of Surgeons, London, are eight feet six inches, and eight feet two inches respectively. Goliath is reported by Josephus, to have been four cubits and a span (about eight feet nine inches) and Og, King of Basan, said to have been the last of the giants, (Deuteronomy, 3,11) occupied an iron bedstead measuring nine cubits, (about thirteen feet).

It must be remembered that in mythology and folklore, the term giant was often applied to an individual of great speed, strength, prowess or endurance, even if he did not possess great stature or size; a fact which explains the frequent reference to their existence and exploits.

---

*Read before the Philadelphia Pediatric Society, June 13, 1922.

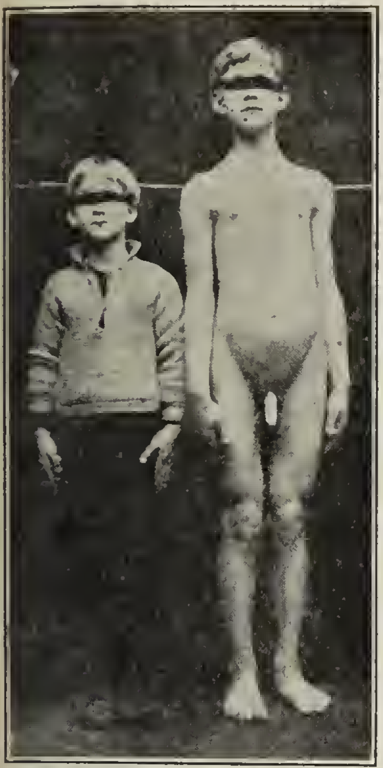

Fig. 1.—The line on the wall represents the average normal height for a boy eight and a half years of age.

An arbitrary classification by Bollinger, places all persons exceeding 205 cm. (six feet ten inches) as giants. This standard may serve as a working rule, though we know from anthropometric studies that there is a mean standard of height in every race, with a few departures in both extremes, and it is not improbable that an occasional individual within, or beyond, Bollinger's standard, may be the normal extreme for his race.

Launois and Roy have given us a more acceptable definition of gigantism as "an anomaly of skeletal growth which leads to a height of the body in excess of the average dimensions of the race and is associated with a characteristic morphological and functional derangement." This of course excludes the socalled "normal giant," a type described by Carl von Langer following his anatomical study of giants in 1872.

Pierre Marie first discussed the pathogenesis of gigantism calling attention to its association with acromegaly, and Biedl defines it as "the acromegaly of those individuals, irrespective of age, whose epiphyseal cartilage has not undergone ossification. This definition is only applicable to those cases of excessive growth due to some malfunction of the pituitary, a condition which is almost invariably associated with an arrested development of the genitalia; the syndrome termed eunuchoid gigantism. Cushing however, says that "illustrative cases of undoubted hyperpituitarism in childhood have been rare and it may be found that premature sexual ripening characterizes this condition."

Tumors of the pineal gland occurring in childhood are accompanied by excessive growth, precocious mental and sexual development and if the lesion is extensive enough, symptoms of brain tumor; particularly those of quadrigeminal lesion. In adults only the neurological signs and symptoms are seen.

Tumors of the suprarenal cortex in childhood may be associated with excessive body growth and premature genital development; a clinical syndrome not dissimilar to that occuring in tumor of the pineal.

Hypergenitalism on the other hand, may be associated with lesions of the pineal, suprarenal or pituitary glands, and is in some cases attributed to primary hyperplasia of the interstitial cells of Leydig.

These abnormalities of skeletal growth and sexual development may be attributable to the malfunction of a particular gland, though the similarity in the syndromes resulting from disease of such widely separated structures as the pituitary, pineal, suprarenal, or interstitial cells of Leydig would make more tenable the assumption that the changes are brought about through an imbalance or disharmony of function in the group of glands rather than in one of them.

The cases which I am presenting, show in association with the abnormal skeletal growth, a precocious onset of puberty.

The patients are brothers, aged eight and a half and seven years. They were born in this country of Lithuanian parents. The maternal grandmother and two maternal aunts were large women. The father was a large bigboned man. He died after five days illness during the influenza epidemic.

The mother is a small frail woman weighing ninety-eight and a half pounds. Height four feet eleven inches.

Case I.—W., aged eight and a half years, was born in normal labor. He weighed nine pounds at birth, was breast fed and had no diseases except pertussis and measles. His height is five feet one and a half inches, weight one hundred pounds. He is of the blond complexion characteristic of his race and has the general appearance of a boy of fifteen years of age. There is no noticeable enlargement of the pneumatic spaces. The facial features are small with a tendency to concavity of profile. There is a suggestion of maxillary prognathism. The mandible seems small in proportion and shallow in depth. The upper teeth are widely spaced. The laryngeal prominence is noticeable. The general body nourishment is poor with no localized deposits of fat. The hands and feet are disproportionately large (shoes size seven). The genitalia show full pubescent development. The pubic hair is well developed with a feminine distribution. There is a good growth of axillary hair and a downy growth of beard. The blood count is normal save for a slight eosinophilia (eight per cent.). The blood sugar findings and sugar tolerance tests were normal. The urine showed a slight trace of albumen. The x ray report showed the sella turcica about average size or slightly smaller than the average with rather prominent clinoid processes. The hands and feet are unusually large with relatively long phalanges. The epiphyses are so developed as to appear like those of a boy of from twelve to fifteen years of age. Examination of the eyegrounds showed no signs of intracranial pressure. The mental development is normal for his age. A suggestion of immaturity or childishness in some of the mental reactions is merely an objective discrepancy between the actual eight year mentality and the physical appearance of a more advanced age.

Case II.—A., aged seven years, was born in normal labor and weighed six pounds three ounces at birth. He was breast fed and had pertussis and measles. His height is four feet three inches. Weight fifty-nine and a half pounds. In physical structure and appearance he resembles his brother. The facial contours are similar. The feet and particularly the hands, are clumsily large. He has the appearance of a boy about ten years of age. The genitalia have undergone pubescent development with a noticeable growth of pubic hair. The blood count shows a low hemoglobin (seventy-two) and sugar findings were normal. The urine showed a trace of albumen. The x ray report is as follows: "the sella turcica is probably smaller than the average for the size of the head. The clinoid processes are larger anteriorly than, posteriorly. There is no irregularity in the floor. The bones of the arms and hands, legs and feet, are relatively larger and the epiphyses are developed so that they look like those of a child from twelve to fifteen years of age. We believe that there has been at some time, if not at present, increased intracranial pressure. The convolutional depressions are more pronounced than normal and there is slight separation of the coronal sutures."

The eyeground examination shows no signs of intracranial pressure. The mental development is normal for his age. In conclusion I wish to emphasize the followings points:

1. The abnormal skeletal growth of thirteen and a half inches above the average height for his age, in a boy eight and a half years old and six inches above the average in a boy of seven years.
2. The precocious onset of puberty in association with the abnormal skeletal growth.
3. The normal mental development according to age.
4. The occurrence of the condition in brothers with the suggestion of an hereditary component.

In view of the positive findings and in the absence of symptoms suggesting involvement of other glands, it seems safe to assume that the condition is due to a hyperfunction of the anterior lobe of the pituitary gland.

X Ray Therapy of the Thyroid Gland*

By JOHN G. WILLIAMS, M.D.,

Brooklyn.

Our knowledge of the physiology of the thyroid gland is like that of many others of the ductless glands, somewhat incomplete. We know that congenital deficiency of the thyroid results in failure of physical and mental development, which condition is known as cretinism. When this deficiency begins in adult life there results a group of symptoms such as mental and physical sluggishness with edema and reduction of basal metabolism, and we designate this syndrome as myxedema or hypothyroidism.

The active principle of thyroid secretion is an iodine compound. According to Marine the iodine is stored in the gland in two forms. The physiological active hormone is stored in the colloid of the gland, while the inactive iodine collected from the blood is stored in the cells to be elaborated into the active form as needed.

In mammals it has been shown that the normal thyroid contains on an average 0.2 per cent. of iodine with extremes of 0.1 and 0.5 per cent. It has also been demonstrated that, whenever the store of iodine falls below 0.1 per cent., active hypertrophic and hyperplastic changes in the thyroid take place. This iodine store in the gland may be rapidly increased by the administration of iodine in almost any form, and as a result of this, hypertrophic and hyperplastic glands in the young rapidly undergo involution with return of thyroid cells to normal or nearly so.

Kimball and Marine, applying Marine's observations on the rôle of iodine in goitre prevention, in known goitre districts, demonstrated that the administration of small doses of iodine to school children of these districts markedly reduced the incidence of thyroid enlargement in adolescents, and reduced the size of the gland in those already affected.

Kendall isolated the active iodine compound of the thyroid which he called thyroxin. This compound when administered to patients with myxedema has the same physiological effects as desiccated thyroid gland. Plummer has shown that the intravenous administration of ten mg. thyroxin to a patient with myxedema elevates the basal metabolism rate twenty-eight points. The maximum elevation is reached five to ten days after administration and does not return to previous rate until thirty to forty days later. Clinically he has determined that the daily administration of 1.6 mg. thyroxin is the average requirement of an ordinary case of myxedema.

Cannon and Smith have shown that stimulation of cervical sympathetic causes increase secretion of thyroid. Severing the nerves to the gland apparently causes no serious disturbance and he believes that the nerves serve emergency function to the gland in times of stress.

Marine sums up the function of the thyroid in the following way: "The thyroid has to do in some important way with internal respiration, or the utilization of oxygen by the tissues. Indeed this is the only known function of the thyroid."

We may classify goitres as simple, cystic, colloidal, adenoma, exophthalmic, and malignant.

Of these the adenomata with hyperthyroid symptoms, the exophthalmic and malignant cases are suitable for x ray therapy. It would seem to be proper to classify the toxic adenomata and exophthalmic goitres as cases of hyperthyroidism.

Advanced cases of hyperthyroidism are so characteristic that the diagnosis is not difficult. In certain cases, however, in addition to the history and physical examination it is necessary to resort to a determination of the basal metabolism or Goetsch test for diagnostic purposes. Usually a basal metabolic rate in excess of plus fifteen is found in hyperthyroidism. The metabolism test is a valuable aid in determining the progress of the case while under treatment. R. S. Dinsmore, in a recent work on the thyroid gland by G. W. Crile and associates, sums up the results of the Goetsch test in this clinic as follows: 1. "The Goetsch test has been of distinct value to us in the differentiation of borderline cases of hyperthyroidism. 2. Eighty-nine per cent. of the patients with clinical symptoms of hyperthyroidism give a positive reaction to adrenalin. 3. In about eighty-five per cent. of the cases the results of the Goetsch test are in agreement with the metabolism estimations. (Basal metabolism estimations themselves are distinctly less than one hundred per cent. accurate.)"

---

*Presented before the Society of Internal Medicine, Brooklyn, New York, October 27, 1922.

The x ray treatment of hyperthyroidism dates back many years. In the early days of this treatment these cases were usually treated by fractional doses, usually with no filtration and frequently with no accurate measurement of dosage. Obviously under such conditions there were frequently severe reactions of the skin induced, accompanied by the immediate symptoms incident to such injuries and later followed by permanent changes in the damaged skin, such as telangiectasis, atrophy and other sequellæ. Naturally as a result of these injuries, this method of treatment did not become popular. However, with the development of more accurate determination of dose, and the advent of filtration and the invention of the Coolidge tube, this branch of x ray therapy was again taken up and in recent years a large number of papers on this subject have been published.

It has long been known that in many cases of hyperthyroidism there is also hypertrophy of the thymus gland. According to Blackford and Freleigh of the Mayo Clinic, all patients under forty years show enlarged thymus and about fifty per cent. of those over forty show this condition. Because of age incidence they conclude that the presence of enlarged thymus in these cases is due to toxic condition incident to the goitre which stimulates hypertrophy of vestigial remnants of this gland. Because of the common association of enlarged thymus in these cases Halstead tried the x ray treatment of the thymus and in 1916 reported in the *Johns Hopkins Hospital Bulletin* satisfactory results. In his cases treatment was administered to anterior mediastinum, but no treatment was given over the thyroid area. Pfahler and Zulick in 1916 in a comprehensive review of the literature and based on their experience conclude that "no case of Basedow's disease should be operated on until there has been a trial of röntgen treatment. If the indications call for operation later, the patient will be in a better condition for the operation after the treatment than before. They advise treatment to both thyroid and thymus regions.

G. W. Grier in 1917 concluded that in mild cases of hyperthyroidism rest or x ray treatment were indicated and surgery contraindicated. In acute exophthalmic goitre x ray treatment is the most satisfactory. Surgery is unnecessary and dangerous. In long standing cases the choice lies between x ray treatment and surgery. The x ray treatment is apt to be slow but there is no mortality and less danger of subsequent recurrence.

J. A. Lichty says that eighty per cent. of cases of exophthalmic goitre can be symptomatically cured by radiation and also advises preoperative treatment where operation is contemplated and postoperative treatment in recurrences after operation.

Holmes and Merrill in 1919 reported results of treatment in 262 cases. In 1921 they reported on 107 additional cases. Their conclusions are that colloidal, cystic and simple goitres should never be rayed. Malignant disease should be treated surgically and receive postoperative raying. Toxic adenomata respond readily to x rays but surgery is quicker and mortality in these cases is low.

Nontoxic adenomata are treated surgically if at all. None of these have been rayed. Exophthalmic goitres are usually started on rest and radiation. Even if surgery is contemplated preliminary rest and radiation reduces the operative risk. As a matter of fact a large percentage of cases never come to operation.

A. F. Tyler, of Omaha, in a paper before the American Röntgen Ray Society, speaking of the advantages of x ray therapy of toxic goitre over other methods, says that first, there is no mortality due to treatment; second, it is useful in surgical failures; third, it can be employed in operable cases.

A. H. Soiland, of Los Angeles, sums up his experience in treatment of two hundred cases of toxic goitre as follows: "It is not the intention of the writer to decry surgery or detract one iota from the many brilliant results obtained by competent operators, but the fact must not be lost sight of that in radiation we have a proved therapeutic agent, far superior to any other given us up to the present time."

R. G. Allison, A. H. Beard, and G. A. McKinley report on work in the x ray laboratory of the medical department, University of Minnesota: "The cases were classified in three groups; first, those exophthalmic cases receiving only x ray treatment; second, postoperative cases with persistant symptoms; and, third, three cases of toxic adenoma." A large number of their cases were checked up by metabolism tests. They summarize the results in graphic charts. In the cases receiving only x ray treatment the average metabolism rate before treatment was plus thirty-two and after treatment plus nine. In the postoperative cases before x ray treatment the average was plus twenty-eight and after treatment plus twelve. The toxic adenomata consisted of only three cases which showed little change.

Seymour summarizes the advantages of x ray therapy of hyperthyroidism as follows:

> There are no fatalities. There is no resulting scar as after operation. It does not interfere with the patient's occupation except in severe cases. It is painless and causes very little inconvenience to the patient. If unsuccessful, an operation may be performed with less work because of the favorable action of the x ray on the thymus gland.

Florence Story in 1913 reported forty-eight cases of hyperthyroidism treated with x ray. Of these fourteen were cured, twenty-two improved, four unimproved and seven did not continue treatment.

Probably the largest group of cases reported on in which there were careful metabolism studies made is that reported by Means and Aub. The basal metabolism in those treated with x rays averages plus sixty-three, whereas in those treated surgically the average before operation was plus forty-six. Therefore those treated with x rays showed higher degree of toxicity. The basal metabolism in those treated surgically dropped sooner than those treated with the x rays. This early drop in the surgical cases was, however, soon followed by a rise in the rate. Tests of both groups at the end of three years showed the same results, each group averaging plus thirteen per cent. Of nine deaths in fifty-five cases five were due to surgery. One died during x ray treatment of exophthalmic goitre. Three died of unknown causes. Their conclusions are as follows:

1. Results are equally good with surgery or x rays after two to three years.

2. After surgery the metabolism shows a rapid preliminary fall, a second rise followed by a final fall. That with röntgen ray treatment there is a gradual progressive fall.

3. That in securing the same results with surgery or röntgen rays a lesser rest factor is necessary with x ray treatment. With x rays there is no mortality; with surgery there is a definite mortality.

4. That patients treated surgically do better and the risk of operation is less if they have previously had their thyroid and thymus glands irradiated.

5. That risk of operation is greater and need for preoperative röntgen ray treatment is greater in cases with a very high metabolism and moderate tachycardia, than in those with extreme tachycardia and moderate metabolism elevation.

6. That the safest program for the treatment of exophthalmic goitre as a whole is the röntgen irradiation of the thyroid and thymus glands in all cases, with surgery reserved for those who do not do well.

7. That surgery is contraindicated with patients whose metabolism is rising in spite of complete rest in bed and also with patients of the type with moderate tachycardia and great metabolism increase except when they have previously had thyroid and thymus glands treated by röntgen ray.

Most of the opposition to x ray treatment of hyperthyroidism is voiced by the surgeon. C. H. Mayo, in a paper before the Clinical Congress of American Surgeons in Montreal in 1920, said: "With x ray treatment remission may occur just as remissions occur without treatment or with several other methods of treatment. Our experience has been failure or but temporary benefit. It is possible that the ray treatment may destroy the gland and produce hypothyroidism. It is difficult to regulate the dosage and its use adds to the difficulty of operation. It is to be hoped that radiotherapy may be developed into a safe and effective method of securing a cure or relief in preparation for surgery." His conclusions concerning results of x ray therapy differ so materially from the many röntgenologists and internists reporting on this subject that they are not to be reconciled. Apropos of the production of hypothyroidism by x ray therapy, he mentions the study of one hundred cases of myxedema and hypothyroidism in this same paper and ascribes the causes to thyroiditis, inactivity of the gland and surgical excess. He makes no specific mention of x ray therapy as a cause.

Crile in a paper published in 1921 quotes various authors who favor or oppose x ray therapy in hyperthyroidism. He says that the operative risk under this type of surgical management may be largely disregarded, yet Mayo in his paper while not giving definite mortality statistics, says the death rate may vary from 0 to four per cent. in groups of one hundred. Crile alludes to the danger of x ray burns and the possibility of damage to the parathyroids. Burns in these cases are possible, just as death from hemorrhage is possible in the surgical treatment, but neither of these accidents should occur. I am unable to find any reports of damage to the parathyroids through x ray therapy, though there are many reported due to surgery. Concerning the danger of myxedema from x ray therapy the following quotation is from a chapter by C. D. Christie in a recent book: "Most of the adult cases of myxedema which we have encountered have followed thyroidectomy. We have, however, encountered myxedema in patients on whom thyroidectomy has not been performed." In the same chapter Christie says: "The tabulations serve to emphasize the fact that rest and exposure to the x ray, ligation and thyroidectomy are all very potent factors in reducing heightened metabolism, the basic symptom of exophthalmic goitre, and therefore favorably affect the course of the disease. It will be found that the pulse rate represents a fairly accurate index to the metabolic rate."

I have in the past treated hundreds of cases of cervical adenitis and cancer of the breast in which the thyroid region was incidentally subject to radiation and yet I have never known of a case of myxedema following these treatments. It would therefore appear that there is no great danger of hypothyroidism following radiation. Holmes and Merrill in their large series report one case of myxedema. S. G. Burnett reports a case of myxedema following radiation, but there was nothing in the history of this case as given to warrant the use of the x rays, there being practically no evidence of hyperthyroidism.

The x rays in hyperthyroidism apparently act by causing atrophy and diminished activity of the epithelium of the vesicles. E. Goetsch and C. A. Waters in some experimental work on dogs demonstrated that after intense x ray exposures there resulted changes in the thyroid varying from moderate atrophy to almost complete destruction of secretory power of the gland. The treatments given in these experiments were, however, several times more than a safe dose in human beings. There was sloughing of the skin at the time the dogs were killed. The technic as used by me has been to treat the thyroid and thymus areas on each side separately, using four mm. of aluminum as a filter—nine inch spark-gap at a distance of nine inches for six minutes to each area. Latterly where the tonsils show marked hypertrophy and evidence of disease, I have included them in the area to be treated, extending the distance to twelve inches and time to nine and one half minutes. The second treatment is given three weeks later and the third treatment four weeks after the second, the interval between treatments being extended one week longer than each preceding interval. In this way I believe there is no danger of giving too much treatment. This is not a routine treatment for all cases, as the cases vary in their degree of toxicity and the amount of treatment given varies accordingly.

Only rarely have I noticed much change in the patient's condition three weeks after the first treatment. Plummer's finding that the effects of a single dose of thyroxin continues for thirty to forty days after administration I believe explains the delayed response to treatment. Usually at the third visit seven weeks after the first treatment there is noted a slowing of the pulse rate and an amelioration of the nervous symptoms. After this the patient begins to regain some of the previous loss in weight. The eye symptoms and the goitre are last to show improvement and frequently do not wholly disappear. The number of treatments necessary varies from three to nine with an average of about five. Cases treated by me since 1916 vary from mild hyperthyroidism to intensely toxic cases. Fifteen per cent. of cases treated have previously had surgery with persistence of symptoms. These have generally improved under treatment. One case recently treated by me discontinued treatment unimproved after three treatments. Four years previously he had had a double ligation. He had no visible or palpable enlargement of the thyroid nor did x ray films show any evidence of intrathoracic goitre. He was actively engaged in business during treatment, and I believe he would have shown some improvement could he have rested while under treatment. A considerable number of cases treated by me have been able to follow their usual vocations while under treatment. However, I believe that rest and freedom from worry and excitement when possible, together with medicinal treatment if necessary, are necessary concomitants of x ray therapy. Highly toxic cases should have rest in bed to prevent damage to the myocardium.

Very little has been written on the x ray treatment of malignant disease of the thyroid. Pfahler in a paper before the American Röntgen Ray Society in 1921, reports a series of cases, some of which had been operated on and were referred for postoperative therapy; the balance of the cases were tumors of the thyroid, some of which were proven by microscopic section, but in others the diagnosis was based only on the history and clinical findings. In general the results showed disappearance of primary tumors or local recurrence. Where metastases had taken place before treatment was begun, there was little response to treatment, and sometimes metastases appeared in remote parts after treatment was discontinued. Richards of Toronto in discussing this paper reported favorable results in two cases of carcinoma proved microscopically.

Crile reports an inoperable case of carcinoma in which, following division of the preglandular muscles to relieve pressure, symptoms entirely disappeared under x ray therapy. Five months later the patient was apparently well except for symptoms of myxedema due to destruction of gland by the growth. My own experience in those cases has been limited to postoperative therapy. One case with extensive involvement of cervical glands showed marked improvement but discontinued treatment because of röntgen sickness induced by treatments and has not been traced. Sufficient time has not elapsed in the other cases to determine final results.

All cases of hyperthyroidism should be treated with rest and x ray therapy.

Those cases not completely cured are better surgical risks after this treatment.

X ray therapy is indicated where symptoms persist after surgery with prospect of relief.

In malignant disease of the thyroid surgery is indicated when complete removal of growth seems possible, to be followed by prophylactic radiation. If inoperable, intensive x ray therapy offers probability of some relief and possibility of cure.

Congenital Total Hemihypertrophy*

By ALFRED C. REED, M.D.,
San Francisco,
Associate Clinical Professor of Medicine, Stanford University Medical School.

The recent report by Stanton and Tuft (1) of a case of this interesting and unusual condition prompts me to record a similar case seen in the medical service of the Stanford University Medical School in the fall of 1919. In a thorough review of the literature, these authors find a total of only forty-one reported cases, theirs being the forty-second. It is unnecessary to repeat the material they have given on the literature, rarity and pathology of congenital total hemihypertrophy.

CASE.—Miss M. P., aged fifteen and one-half years, an American born girl of Italian parentage, came to the Stanford Medical Clinics for tonsillectomy. In the course of the routine examination for anesthesia, attention was directed to the marked disproportion in size in the two sides of her body. Her right foot, leg, thigh, pelvis, abdomen, breast and upper extremity were considerably larger than the corresponding parts on the left side. There was a disproportion in the shape of the head and face with a considerably wider palpebral fissure on the right but the actual measurements were the same on both sides.

Her father was a syphilitic, who had a Neisser infection, both diseases, however, being contracted after the birth of his two children. The mother was subject to asthmatic bronchitis and had extensive nasal accessory infections. The patient has one brother two years younger than herself, well and entirely normal. All of the grandparents lived to an advanced age and there was no history in the family of congenital structural anomaly.

The patient had been healthy and robust, was born at term and developed normally. She had had diphtheria. She never had headaches, nor was there a history of any injury or accident. For some time the glands in her neck had been swollen. She had never had earache or an ear discharge. Hearing had always been acute. She had had frequent moderate sore throats and for that reason wished to have her tonsils removed. She was not constipated and never suffered any irregularity in the respiratory, cardiac or digestive systems. Menstruation began at the age of eleven and had been normal and regular. She was born and had always lived in California. Her present illness and complaint related solely to her tonsils. The asymmetry of her body was noted on the occasion of examination for anesthesia.

---

*From the Department of Medicine, Stanford University Medical School.

Examination showed a well-developed and well-nourished girl weighing 110 pounds, of bright and intelligent demeanor and no appearance of ill health. The special senses and sense organs were normal. The teeth were excellent, tonsils hypertrophied, cervical glands palpable. The heart was in normal position and presented no abnormality. Lungs were clear. The breasts were unusually heavy, hypertrophic, pendulous, and the right breast was considerably larger and hung lower than the left. The abdomen was asymmetrical, no abnormality found. The right arm and forearm were one-half inch greater in circumference than the left. The right foot was of the same length and breadth as the left, but the foot, the calf and the thigh were one inch greater in circumference. The disproportion was striking.

The skin showed peculiar lesions limited to right side of body, which Dr. H. E. Alderson, professor of dermatology in the Stanford Medical School, described as diffuse areas of passive congestion, mostly on the outer aspect of the right leg, thigh, buttock, lumbar and scapular regions. According to the patient these areas did not vary in location but did vary in intensity. At times the redness or bluish tinge would be deeper than customary. The localized unilateral and extensive distribution of these lesions suggested an origin in some central nervous influence affecting the vasodilators.

X ray examination of the skull showed a sella of normal size and with its floor clearly outlined, and no radiographic abnormality of the skull.

Blood pressure was equal in the two arms and averaged 105/75. Pulse averaged 76. Temperature was normal. Blood Wassermann was negative. Blood count showed 4,440,000 red cells, 85 per cent hemoglobin, 7100 leucocytes with 60 per cent. polynuclears, 34 per cent lymphocytes, 2 large mononuclears, 2 eosinophiles and 2 transitional cells. The urine and blood sugar tolerance were normal.

In summary, no clew to the cause of the one-sided hypertrophy could be found. It was evidently on a congenital basis and there was no definite evidence of endocrine unbalance or asymmetry of the vascular system. The peculiar skin lesions raise the possibility of increased blood supply to the right half of the body but it is only a supposition.

The Newer Aspects of Röntgenotherapy*

By CHARLES EASTMOND, A.B., M.D., F.A.C.P.,

Brooklyn, N. Y.

In any consideration of new methods, it is advisable to review briefly the old, and to take stock of what has already been accomplished. This holds especially true of röntgenotherapy.

It is to be remembered that, in a general way, the x ray is an irritant. Mild irritation from any cause provokes stimulation; excessive irritation, or overstimulation, always produces destruction. The physiological action of the ray, or the rationale of röntgenotherapy, constitutes this very effect—stimulation of such tissues as may require an alteration of the local metabolism of the cells, or destruction of pathological tissue, whether it be superficial or deep.

The conditions in which röntgenotherapy is applicable divide themselves into three groups, in accordance with their accessibility or their more ready response to irradition: The superficial lesions of the skin; glandular system; deeper structures.

Röntgenologically, superficial lesions are those dermatological conditions which are benefited, if not entirely cured, by the proper application of the x ray.

Before considering the individual conditions in which this therapy is indicated, certain peculiarities must be taken into account. Skin susceptibility varies with age, sex, color, and the part of the body exposed, and the technic must be modified accordingly. Superficial action and reaction are also intensified by certain chemicals, such as iodine, chrysarobin, sulphur, mercury, tar and salicylic acid. Accordingly, if any of these agents has been employed prior to irradiation, the greatest care must be exercised to avoid an undesirable dermatitis.

From the röntgenotherapeutic viewpoint, dermatological conditions are divided into certain groups, in accordance with the nature of the pathology, and the change to be effected.

a. Those conditions in which it is desired to produce a change in the local metabolism of the cells. The most common conditions in this group are acne, eczema and psoriasis.

Acne.—The types most favorable to irradiation are the indurated and pustular forms which respond readily and offer most brilliant results. However, even the simple, acute pimples of the growing girl may be eliminated. The acne which appears only at the menstrual period does not respond well to radiation, but this is usually effectively treated by other means.

Eczema.—Eczema of the chronic type is almost invariably relieved, with complete restoration of the skin to its normal condition.

Psoriasis.—This lesion is always resistant to chemical treatment, and irradiation alone brings about only temporary relief. A series of x ray treatments, followed by the use of chrysarobin, is frequently the most effective means.

---

*Read before the Brooklyn Medical Society, December 15, 1922.

2. The second group is comprised of those conditions in which there is infection of the hair follicles. Here, epilation is indicated, not only to remove the infected hair, but also to permit complete drainage of the hair follicles.

Folliculitis, ringworm, and sycosis.—These are the most prominent types of hair follicle infection, and the loss of the hair—incident to the action of the ray—will usually cure the condition. While alopecia is thus produced, the baldness is only temporary, and, as a rule, the hair returns in increased quantity within three months.

3. The third group includes those conditions necessitating the destruction of tissue.

Verruca vulgaris.—Verruca vulgaris or the common wart, together with callosities, is readily destroyed, disappearing often after a single application.

Keloid.—Röntgenologically, this may be considered to be of two types. The first, the traumatic, occurs after burns or scalds, and is amenable to treatment. The second, or surgical, is present when there is excessive cicatricial formation at the site of an operative wound. The latter is more resistant, but when such scar tissue interferes with the function of a joint, sufficient diminution can be accomplished, so that joint function is increased to the point of usefulness. Of particular importance, in keloidal conditions, is the relief from pain when it is present.

Lupus.—In lupus where destruction of the affected tissue is the end to be attained, the results are good.

Rhinoscleroma.—While unusual, rhinoscleroma must be included because the x ray is practically a specific in this condition, and the outcome is far superior to that obtainable by any other method.

The spleen and lymphoid structures are very susceptible to radiation and consequently, in disease of these structures, röntgenotherapy is the advisable procedure. The most common splenic conditions are splenomyelogenous leucemia and the splenic enlargements associated with certain forms of anemia, including Banti's disease. In none of these conditions s a permanent cure effected, but life is prolonged for two to five years.

The best results are obtainable only when there s the closest cooperation between the röntgenologist and the attending physician. The importance of this cooperation is readily appreciated when one considers hat the physician must observe his patient closely for he earliest sign of relapse, in order that further reatment may be instituted; and must report the paient's systemic reaction to treatment, so that the dose may not exceed the point of tolerance.

Hodgkin's disease.—As an affection primarily of he lymphoid structures, Hodgkin's disease offers the strongest indications for röntgenotherapy. Treatment of each affected area, including the mediastinal glands when they are involved, prolongs life—as with splenic conditions—for from two to five years. Reapses are frequent, and again, as in splenic condiions, the patient must report frequently.

Tuberculous glands.—Even in the early days, with he crudest of technic, tuberculous glands were reduced in size, and röntgenotherapy is still the procedure of choice. The results in these cases are extremely satisfactory, and the patient is spared an unsightly operative scar. If the glands break down, a simple puncture for drainage is sufficient when the x ray is used.

Thyroid.—As this is a glandular structure, it is also in this class. In thyroid cases, their order of response to the ray is important: 1, the exophthalmic; 2, the toxic, and 3, the cystic.

When the thyroid is being treated by röntgenotherapy, the joint observation of the röntgenologist and the attending physician should continue for at least six months. On the part of the physician, this observation will consist of a careful record of the pulse, weight and basal metabolism rate. Complete abolition of the tumor mass may not be accomplished, but the relief of the exophthalmos, the diminution of the pulse rate, the diminution of the basal metabolism, and the increase in weight, all will indicate that the patient's condition has been ameliorated.

It is of especial interest that the newer technic, permissible with the high voltage apparatus, materially shortens the course of the treatment, so that the patient may now receive, within two weeks, an amount of irradiation which was formerly possible only over a long period of time.

Tonsil.—Being also lymphoid tissue, the tonsil must receive consideration. Theoretically, irradiation should bring about a rapid destruction of the glandular tissue, so that practically nothing but the stromal elements would remain. Brilliant results have been reported by some, while others who are equally reputable as röntgenologists and equally careful as observers, have failed to attain the same ends.

It is my opinion that the röntgen treatment of tonsils should be limited to children, and, possibly, to those adults who are considered unsatisfactory surgical risks. Sufficient time has not yet elapsed to determine the permanence of the results.

Ovaries.—The effect of the x ray upon the ovaries is most profound. By careful regulation of the dose, mere diminution of the ovarian function is effected; while, with large doses, all functioning can be completely terminated, and a true menopause produced.

There are a number of women in whom abnormal ovarian function manifests itself by an excessive menstrual flow. The menorrhagia referred to usually occurs before thirty, and I have observed it in a girl as young as nineteen. These cases are to be differentiated, however, from the ovarian disturbances incident to the menopause. The excessive menstrual flow (menorrhagia) is readily controllable, so that there is a return of the periods to normal. However, in those women who are approaching the time of the menopause and who are suffering from uterine hemorrhage, metrorrhagic in character, a permanent cessation of ovarian function is effected, with practically no disability to the patient. The presence of a fibroid is an indication for, rather than a contraindication to, röntgenotherapy.

Uterine fibroids.—With the exception of those cases in which the physician may be reasonably certain that the growth is pedunculated and intrauterine, or in the presence of a single mass which may be removed without disturbing the integrity of the uterus as a whole, the surgical treatment of fibroids, during the child bearing period, is unwarranted. Not only is there no occasion, but there is no excuse, at the present day, for the removal of a uterus merely because fibroids are present.

For over ten years, even with inefficient apparatus, as therapeutic apparatus is now rated, patients have been wholly relieved of fibroids and restored to complete health, with less physical discomfort than that associated with a simple anesthetic. With modern apparatus of the high voltage type, sufficient irradiation may be given, within three to four consecutive days, to abolish the tumor, and to produce, after a lapse of a few weeks, a uterus which is perfectly normal in form, mobility and size.

It has previously been considered, and is even now maintained by many, that the retrogression of the fibroid is due merely to the production of the menopause through the cessation of ovarian function. This is the teaching of the German school. However, it is common knowledge that many fibroids persist after the cessation of menstruation, and some even develop after that time. It must, therefore, be considered that, in addition to whatever changes may be brought about through the production of a menopause, there is a direct action upon the growth itself, as maintained by Beclere and his followers.

The röntgen treatment of fibroids is by far preferable to the surgical procedure, because:

a. There is absolutely no mortality.

b. The shock is relatively slight, and is entirely recovered from within a few days.

c. There is no anesthesia risk. While this is small, it must be considered when one undertakes a major surgical procedure.

d. The psychic effect produced upon the patient when she realizes that there will be no loss of a body organ, but merely its restoration to the normal.

It is to be noted, however, that adnexal inflammatory conditions contraindicate röntgenotherapy for the control of ovarian function or for the abolition of uterine fibroids.

Carcinoma.—A consideration of röntgenotherapy in connection with the cancer question includes the entire gamut of malignancy from the superficial basal cell epithelioma to the extensive primary or recurrent intraabdominal growth.

It is recognized that the nearer body cells approximate embryonal tissue, the greater is their reaction to radiation. Therefore, malignant tissue, being embryonal in type, lends itself readily to removal by this means. There is absolutely no question but that the rays will effect an elimination of malignant tissue, as it is necessary only to introduce the requisite amount of ray into the affected part.

It has been erroneously asserted that the rays tend to promote the growth of preexisting malignancy, and that, under irradiation, tumors will enlarge. Dr. James Ewing, of New York, who has studied extensively the subject of the rays and cancer, denies absolutely such a possibility. The enlargement of cervical glands, etc., is merely a primary inflammatory reaction, such as ensues after the exposure of normal tissue.

The socalled "lethal dose" has been considered essential for the elimination of malignant tissue. However, it is advisable to set aside the older term, in favor of the new "optimum dose." In one of the New York hospitals where much time has been devoted to the irradiation of the deeper structures, the early idea of introducing a maximum amount of ray was followed by poor results and even by death, because of the false impression that the more ray introduced into the tissue the more rapid the destruction and the quicker the recovery. Further experience has demonstrated that, with proper technic, what is spoken of as the optimum dose may be administered with the best results, and, with such technic, the systemic reaction need not exceed the patient's tolerance.

How does radiation destroy malignancy? The question is a natural and pertinent one. In the presence of superficial lesions, it has been considered that there was brought about a necrosis of the malignant tissue, with its replacement by a normal or scar formation. Recent work by Ewing has shown that, in regard to tumor cells, there is usually excess pigmentation of their nuclei, together with an anemia of the cells themselves, followed by atrophy. During this process, there is a more important change—that of increased activity of the surrounding cells, the advance of leucocytes and lymphocytes, and the proliferation of the capillaries, all of which invade and replace the tumor mass.

In deep carcinoma, the destruction is not brought about by a direct killing of the tumor tissue, but the necrosis is due to occlusion of the delicate bloodvessels, leading to an infarction, and thus, secondarily bringing about death of the tissues. The broken down cells are then absorbed and eliminated by the body. As Ewing well states, "Direct killing of tumor tissue cells is probably never accomplished by external radiation. It is an important law of pathology that necrosis of tissue cells usually results from failure of circulation."

It is not necessary to consider the divers forms of malignancy in their special localities. Practically all malignancy is amenable to röntgen treatment and the results are better than those obtained through any other method. Amelioration is the word at present, rather than cure.

For years röntgenologists have been advocating the use of the ray following the removal of malignant masses, especially those of the breast, as a prophylactic against recurrence. This is of the greatest importance and should be instituted as soon after operation as is possible. It is not necessary to wait for the surgical incision to be completely closed before starting the treatment. However, if postoperative raying is of importance, as has been demonstrated for so many years, preoperative treatment is of even greater importance. The rationale of such a procedure, especially in breast cases, is to block all the lymphatics, in order to limit at the time of operation the possibility of extension, by the passage of malignant cells into the blood stream or lymphatics, with consequent metastases. Often, the breast which has been subjected to preoperative irradiation escapes removal because of the marked recession of the growth.

The question of biopsy has been discussed extensively. It is seldom appreciated that a doubtful tumor may be so irradiated that biopsy will be rendered a safe procedure, and yet the alteration of the tissue will not be so great as to interfere with the pathologist's recognition of the nature of the growth.

In connection with the cancer question, one important point must be borne in mind. The patient in whom cachexia has begun to appear is so overwhelmed with malignancy that nothing will be of any avail, and, if a beneficial effect is to be obtained, treatment must be given before cachexia appears.

Modern methods and high voltage machines have been mentioned. By modern methods is meant a careful plotting out on cross section charts of the location of the lesion to be treated, estimating mathematically the depth from the surface in the case of an internal growth, and considering the best avenues of approach for irradiation. This is done with great accuracy, and, from such a chart, the röntgenotherapeutist estimates how the optimum dose may be administered to the desired point beneath the surface, without injury to the skin.

Modern methods of treatment, especially in deep malignancy, necessitate the use of rays produced by an apparatus which will deliver at least 200,000 volts.

It is generally accepted that the most effective rays for therapeutic purposes are the gamma rays of radium. So far as the physicists can tell us, x rays, produced by a high voltage machine, properly filtered, are identical with the gamma rays of radium. When one considers that it would require from two to three grams of radium on the surface to produce an amount of ray equivalent to that obtainable through the high voltage machine, the superiority of x radiation is apparent.

1. The successful treatment of any pathological lesion by röntgenotherapy is dependent upon the introduction into the tissue of such a quantity of the ray as will produce the desired effect.

2. The destruction of deep pathological tissue by high voltage radiation is a major procedure. There must be definite preparation of the patient before the institution of such treatment, and, following the treatments, the aftercare under the cooperative supervision of the röntgenologist and the attending physician is of the greatest importance for the comfort and welfare of the patient.

3. With modern high voltage machines, the patient receives irradiation of the same quality as the most desirable rays of radium, and in a volume which cannot be obtained from radium because of the large quantity necessary.

4. High voltage röntgenotherapy, in competent hands, is doing more for the relief of malignancy and certain other types of tumor than any other means which has yet been placed at the disposal of the physician. Furthermore, this method of treatment is effective even after surgical failure.

Röntgenotherapy is an accepted institution, an effective agent in the hands of a competent röntgenotherapeutist, and a valuable method of treatment at the disposal of the progressive physician.

Cancer of the Breast: Biological Considerations in Radiotherapy*

By M. J. SITTENFIELD, M.D.,

New York.

Malignancy, with its concomitant fatalities, be it of the breast, uterus or elsewhere, presents today perhaps the same perplexing problem that it has for centuries past. The search for its etiological factors by the best minds, both in the laboratory and at the bedside, has availed us of only negligible and unstable data, notwithstanding the vast amount of knowledge accumulated through the tremendous laboratory and experimental efforts for a better conception of its histopathology, and its pernicious biological behavior. Though until we know something definite of the biological laws that cause or are responsible for tissue overgrowth and tumor formation, we shall be at a loss to understand the various phases of malignancy. To make it clearer let me put it in this way; in one type of carcinomata, the pathological, biological and clinical picture is quite separate and distinct from carcinomata of another group. For instance, the tumors occurring in the tongue are quite different in their malignancy from those of the face. The latter are almost benign in their clinical and biological behavior, in contrast to carcinomata occurring in tongue, breast or stomach, i.e., malignancy is made up of many variables, and it is difficult to ascribe it to one single cause. A search for one unit of causation will most likely be unfruitful, for in every case of cancer there are probably many cooperating factors, one of which predominates in one type of cancer and an entirely different one in another type.

Biological peculiarities are not dependent upon its histopathology alone, but frequently the anatomical part of the organ involved decides the degree of malignancy, dissemination, and metastasis, growth energy, and other physicochemical phenomena. This is especially striking in carcinomata involving the uterus. Here we see it very clearly—a lesion situated in the cervix is generally quite malignant, while, on the other hand, when it affects the fundus its malignancy manifests itself to a much less degree.

Similar degrees of malignancy are met with in carcinomata of the breast. Mammary tumors present themselves in one type as localized growths, remain stationary for a long time, grow rather slowly or not at all, at times without the slightest attempt to metastasize. To all appearances they behave like a benign growth, until all of a sudden they flare up to metastasize in the regional lymph nodes, and thus take on malignant characteristics.

In the second group, however, the tumor growth starts locally in the breast, it does not stay localized very long as in group one, but spreads more or less rapidly in various directions, either by lymphatics into the axillary or supraclavicular regions, or by the blood stream to parts distant from the lesion.

---

*Read before the Clinical Society of the District of Columbia, at Washington, D. C., December, 1922.

There is perhaps another group, in which the malignant degeneration does not start strictly at one definite site but develops probably in more than one area in the same breast. These different foci continue to grow and coalesce to form eventually one large mass. Finally, there is a less common or extreme type where the malignancy is seen in both breasts. The interval between the appearance of a tumor in one breast and then on the opposite side may be so short that they almost appear simultaneously.

From this arbitrary classification it would appear, therefore, that the power and rapidity of metastasizing varies with different tumors in different individuals. In old people, for instance, the growth energy of a tumor is reduced to a minimum, so that the tumor may remain stationary for years. This is also true of tumors that are not very cellular but rather abundant in fibrous tissue. As a broad assumption, it may be said that fibrous tissue tumors grow rather slowly and simulate an attempt on the part of nature to retard the growth. In contrast to this is the richly vascular and cellular group, where secondary deposits are generally found in different organs. To all intents and purposes, they are clinically analagous to the pyemic manifestations of an infection. Whether these pathological phenomena can be attributed to a general lowering of the resistant mechanism of the individual, or to biological factors which render the organism powerless to stop or limit the growth energy of the malignancy, are as yet unsolved questions. Unfortunately, however, we are too often confronted with these conditions in breast tumors. Moreover, these various factors of biological and clinical peculiarities must be recognized and summed up before an attempt is made to take measures to deal with the disease. Neither surgeon nor radiotherapist should attempt to treat cancer without a thorough knowledge of the behavior of malignant tumor, or a familiarity with the anatomical spread of the disease, for any one who slurs any part of the treatment of cancer incurs an untoward responsibility.

For instance, in the therapeutic consideration of the first group in which the tumor is purely local in the breast, with no lymphatic involvement in the axilla, radical surgery will be effective. This type, especially, lends itself very favorably, both anatomically and surgically, to wide and thorough excision, not only of the localized tumor but also of the large field of threatened dissemination. Surgical technic, however, must conform to the localization of the primary growth, i.e., if the tumor is situated on the inner edge of the breast, the surgical procedure must differ from that required for one situated on the outer edge. As a general rule the attempt at surgical removal should be so directed that the tumor excised be in the centre of the field of operation.

Generally speaking, the localized breast tumor, without glandular involvement, comprises the most promising cases prognostically, and offers absolute indication for earliest surgical interference. Recoveries and cures in this class are generally of optimum proportion. Sistrunk, of the Mayo Clinic, reports sixty-four five year cures out of eighty-nine cases where there was no glandular affection. To repeat, this outlook refers only to localized tumors of the breast with no lymphatic involvement.

In the second group where there is already involvement of axillary lymph nodes, or where the lesion is no longer a localized one, in so far as it has already spread and disseminated, an entirely different side of the question presents itself. All statistics show that surgery alone in this type fails to furnish satisfactory results, no matter how radical the excision. At best the permanent five year results are less than thirty per cent., in spite of all attempts at thorough dissection. In this group preoperative radiation is especially indicated. Since, in some cases, surgery alone seems effective, and in others radiotherapy or röntgenotherapy obtains equally favorable results, it is logical to suppose that the intelligent combination of both would offer a still better outlook. This is borne out by the fact that during the past three years, the new technic of röntgenotherapy has received well deserved recognition.

The important physical and biological consideration in the treatment of carcinoma, whether superficial or deep, is to administer an efficient uniform dose of radiation to destroy or annihilate all the malignant disease throughout. How this is best accomplished depends to a great extent upon the personal equation of the radiotherapist. In the first place he should be informed of the exact depth of the lesion from the surface of the skin, and in what direction, in breast tumors, for instance, it is likely to spread or disseminate, whether by lymphatic involvement to the axillary and supraclavicular glands, or by extension, as Handley states, to the deep pectoral fascia. In addition, it is essential that the dose tolerated be carefully calculated by accurate physical measurements, in order to administer with precision an even and homogeneous radiation to the tumor itself.

The proper procedure entails many technical difficulties. In one instance it may be possible to acquire the full dose from one large field using a high focal distance; in another, it may be necessary to ray from two or three or even four areas in order to obtain a sufficient depth dose to knock out all the malignant cells within the anatomical area. This goes to prove that no one rule can be laid down to fit any two cases, the individual equation will often make what would appear at first as an unfavorable outlook into a very promising one.

To meet these conditions it is essential to improvise means to cope with the disease in a given case in the best manner. This will make plain why it is necessary to make use of paraffin blocks in one instance, and in another a rubber bag filled with water, placed over the chest in a manner to obtain an even plane. In this manner we are able to secure increased secondary scattered radiation to enhance the depth dose, and finally bring about even and uniform radiation to all parts of the tumor. To repeat what I have so often said before, all parts of e malignant tumor must receive a lethal dose roughout, otherwise it is hopeless to reckon with a mplete annihilation of the local growth.

At best, even with accurate physical dosing, we il too frequently. For one reason, the biological se for tumors is not a constant, and for another, eater and perhaps more important factors play eir part in the absorption coefficient. In spite of r best efforts in technic, to kill the tumor growth efficient radiation and in the face of possible termination of a lethal dose for cancer, only too ten are we helpless to cope with the disease. Now e question arises, how are we to reconcile these o inconsistent conditions. Our shortcomings must explained essentially on the basis that not sufficient ought has been given to this phase of the question. the first place, we are constantly speaking of a ixed or heterogeneous beam of rays as a physicoemical agent, and perhaps this would serve our rpose if the tissue or cancer cell were purely a ysicochemical reagent, on the one hand to act, and the other to react. But experimentally we know at this reaction can take place only if an interacon ensues, and in this case it means that the cell ust absorb the ray. Perhaps variations in the ility or inability to take up or absorb the ray may count for the differences in the ray absorption of e cancer cells. After all is said, it is not the nount of radiation administered that provokes the sponse, but the amount of ray absorbability of diosensitiveness of the tissue that is responsible for e reaction, and this radiosensitiveness differs in e different tissues, though every tissue reacts to diation in a varied degree, from the most radiosentive tissue to the nerve tissue, which is perhaps the ast radiosensitive. This lack of absorptive power a given carcinoma tissue may possibly explain r failure in spite of our most earnest efforts.

At this point it would be pertinent to state the pression gained from 114 cases of carcinoma of e breast treated by the new intensive radiation in e past two and a half years, some of which have en reported in previous communications. Since e biological and anatomical factors in every case cancer vary, it would necessarily follow that it nearly impossible to establish an exact carcinoma se for every localized tumor. In one instance, 0 to 120 per cent. or even less of a skin erythema se may be sufficient to arrest and destroy the mor mass, in another it may be necessary to apply ree or four times the socalled lethal cancer dose. his may entail technical difficulties in preserving rmal tissue, and in guarding against irreparable mage to the blood and hemopoietic organs. Therere I have modified the plan of procedure by adinistering a maximum radiation of 110 to 150 per nt. of a skin erythema dose to the tumor over a riod of eight to ten days, and await the repair of ood and general health to repeat the dose in four six weeks, depending upon the general condition the patient. It seems to me that there has been unintentional omission on the part of most riters to dwell with sufficient emphasis upon the cessity of maintaining the general constitutional ndition of the individual. It happens entirely too frequently that in the attempts to deal effectively with the malignant tumor, all sense of proportion is lost sight of with regard to the patient who bears the disease. After all, the individual with the lesion must be taken into consideration as to his physical state, his power to react to intensive radiation, possibly cachexia, and other constitutional disorders. Personally I have learned to pay greater attention to the postradiative treatment and also general constitutional tonicity. In this connection it would not be surprising if the good results reported in some clinics abroad were due to the special care given the general condition after the radiation, to the use of intravenous injection of iodine, arsenic, etc., in some soluble form. Since chemotherapy with radiation probably enhances biological effects, it promises greater possibilities. In combination with this the spleen, thymus, and adrenals may also be radiated to stimulate their functional activity to maintain humeral equilibrium.

From this brief and general survey on cancer of the breast, several important points come into view. In the first place, this affliction is as invulnerable and hopeless as it was before the advent of modern röntgenotherapy. A great many of these unfortunates may possibly be spared or at least sustain a symptom free prolongation of life. I hope that no one will gain the impression that radium or x ray, as we know it today, is a panacea for cancer. Far from it. It fails as often as the knife in certain types of cases, and frequently in cases in which surgery fails, it will bring about relief and even apparent arrest of symptoms.

I have taken especial pains to dwell upon our own shortcomings in technic, and also upon the lack of radiosensitiveness of certain types of malignant disease, by its inability to absorb an efficient amount of the radioactive substance. However, I wish to bring this message home to you, that radiation intelligently combined with surgery in the form of preoperative raying followed by radical surgery, and finally intensive postoperative radiation, will effect a favorable result in many socalled hopeless cases.

The real important service to be hoped for from radiation is not alone the destruction of the more or less degenerated cancer cells themselves, but the arrest of the spread of the actively growing cell, i.e., the problem is to attack the cancer cell in full vital activity, to determine how it responds to radiation, and what amount and character of radiation is necessary to destroy it. The reaction from x ray in a carcinoma may not depend only upon the intracellular change in the tumor itself but also upon the effects of the rays upon various processes in the normal tissue, though this much seems to be established, that we are not aware at present of any chemical or physical agent that can influence diseased tissue and leave the normal tissue intact. In other words, it is necessary that advances in pathological knowledge keep pace with the improvement in newer technic, and that both of them be put to a practical purpose.

The sum total of present day röntgenotherapy denotes that we are just in the developmental stage of wave therapy, the surface of which has but been scratched, and as a result we begin to see a little light, though it promises a great deal and many possibilities are in store. The future of radiation therapy of cancer would seem to depend upon a knowledge of the varied response, either direct or indirect, of the tissue to the varied amounts of radiation. This would make for an ideal biological and clinical reactivity, inasmuch as it would offer a measurement of the radiosensibility of a given carcinoma.

A Comparison of the Wassermann and Kahn Tests in Three Hundred and Twenty-Nine Cases*

By JOHN F. ANDERSON, M.D.,
and
EMILY E. FISCHER, B.A.,
Trenton, N. J.

At the laboratory of the New Jersey State Hospital for the Insane about twenty blood Wassermanns and about fifteen spinal fluid Wassermanns are done each week. Of these about five of the blood tests and about five of the spinal fluid tests are from syphilitics under arsphenamine treatment. The other samples are mostly from new admissions at the hospital. It is routine at the hospital to have a blood and spinal fluid Wassermann done on every new admission. The patients are mental cases.

We have had the experience of others with the difficulties of the Wassermann test. The complement may deteriorate. The amboceptor may deteriorate. The antigen may become anticomplementary or lose some of its antigenic properties. These are some of the difficulties. The technic of the test is complicated, the chances of error many. To keep the method of performing the test standard in one laboratory from week to week, being sure that the sheep cell suspension is the same and that the hemolytic system is working the same, etc., is a task; whereas, standardizing the test throughout many laboratories with their varied facilities and personalities seems almost impossible. However, the Wassermann test has been thoroughly tried and in the main has proved reliable.

It is obvious that it would be well for a procedure so important as a serological test in the diagnosis of syphilis to be at once reliable, sensitive and simple enough to be readily standardized through many laboratories. The Kahn precipitation test, as it appears in the current literature, seems to meet these requirements. We felt that we had a good opportunity at this laboratory for trying it. Consequently it was decided that Kahn precipitation tests should be run for a time at this laboratory with the Wassermann tests to see how the results compared.

We used in general the method for the precipitation tests as described by Keim and Wile (1). The antigens were prepared from dried fresh beef heart muscle finely broken up. Fifty grams of this material were placed in a five hundred cubic centimetre Erlenmeyer flask, covered with an inch of ether and placed in the icebox. After twenty-four hours' extraction the ether was yellow; it was poured off and replaced with fresh ether. This was repeated daily for three days. On the fourth day the supernatant ether was water clear. The ether was filtered off and the dried muscle spread out on paper and dried at room temperature until no odor of ether was detectable. To twenty grams of this material was added one hundred cubic centimetres of ninety-five per cent. alcohol and the whole extracted for nine days in the icebox and one day at room temperature. The alcoholic extract was then filtered off. Twenty-five cubic centimetres of this was used as a plain alcoholic antigen. To another twenty-five cubic centimetres of it were added one hundred milligrams of cholesterin.

In the work here reported readings of the Kahn test will be readings of the cholesterinized antigen. A discussion of results with the plain antigen as compared with results with the cholesterinized antigen will also be given.

The cholesterinized antigen was used in a dilution of one part antigen to three parts physiological sodium chloride solution. The plain alcoholic antigen was used in a dilution of one part antigen to two parts of physiological sodium chloride solution. The mixtures were clear and opalescent. They were always used within an hour after dilution. The dilutions were made by rapidly adding the saline to the measured quantity of antigen. It seems important that the antigen be diluted in just this manner. After running for several weeks with good agreement between the Wassermann and Kahn tests, one week we were surprised to find very little agreement between the tests. We were testing nine known syphilitics at the time and whereas we got strongly positive Wassermann tests with their sera, the Kahn tests were mostly negative. On closely questioning the technician who had mixed the antigen it was found that she had made a mistake on that day and had slowly measured the antigen into the required amount of saline and great care was taken thereafter always to mix the antigen in the same way by rapidly adding the saline to the measured quantity of antigen. When this was done there was never a marked disagreement in the results of the two tests. The serum was always inactivated for twenty minutes on the day the tests were performed. The setup of the tests was as follows:

---

*From the Pathological Laboratories, New Jersey State Hospital at Trenton.

Three tenths cubic centimetre of serum was measured into each of three tubes about seven centimetres high, one centimetre diameter. To the first tube was added .05 c. c. of saline. This was the serum control. To the second tube was added .05 c. c. of the plain antigen dilution, and to the third tube was added .05 c. c. of the cholesterinized antigen dilution. The racks of tubes were vigorously shaken for three minutes and then placed in the incubator at 37.5° C. The following morning the tests were read, and, in order to eliminate personal bias, by someone who had not seen the results of the corresponding Wassermann tests. The results were recorded as follows:

—negative precipitation
++++a precipitate of one or more large clumps floating in the serum
+++one large clump or two rather large ones.
++moderate size flocculi
+small flocculi
±fine flocculi (this is a doubtful reaction)

The precipitate is definite so that the results are not at all obscure. The clumps would break up into fine flocculi or granules when shaken. Sometimes in the tests there would be a white suspension near the top of the fluid which differed from the clumps and flocculi in that it disappeared on shaking. There was no mistaking it for a positive precipitation. Hemolysis in a serum did not seem to interfere with the test. If a serum was very cloudy it could not be read, but if only slightly cloudy it could be. Spontaneous (immediate) positive precipitation tests were occasionally noticed but were not recorded.

The Kahn tests and the Wassermann tests were done on the same day. A cholesterinized human heart antigen was used in the Wassermann tests; they were fixed in a water bath at 37.5° C. for one hour; they were read after an overnight period in the icebox.

Of the three hundred and twenty-nine sera tested with both the Wassermann test and the Kahn test, there was agreement between the two tests in 92.4 per cent. One hundred and twenty-two of the three hundred and twenty-nine sera showed some degree of positive reaction in one test or both. Of these, there was agreement between the two tests in 79.5 per cent. Ninety-one of the three hundred and twenty-nine sera were from syphilitics under arsphenamine treatment. Of these ninety-one, there was agreement in the results of the two tests in 80.2 per cent. Eighty-seven of the ninety-one sera from syphilitics under arsphenamine treatment showed some degree of positive reaction in one test or both. Of these eighty-seven, there was agreement in the results of the two tests in 78.1 per cent. Two hundred and thirty-eight of the three hundred and twenty-nine sera were from new admissions at the hospital. Of these there was agreement between the results of the two tests in ninety-seven per cent. Thirty-five of the two hundred and thirty-eight sera from new admissions at the hospital showed some degree of positive reaction in one test or both. Of these thirty-five there was agreement in the results of the two tests in eighty per cent. Tables I and II give detailed results. Table I gives the results with the sera of the ninety-one syphilitics under arsphenamine treatment. Table II gives the results with the two hundred and thirty-eight sera from new admissions at the hospital.

TABLE I

Sera of Ninety-one Syphilitics under Arsphenamine Treatment

	Kahn test	*Wassermann test*
40 sera	++++	++++
15 sera	+++	++++
6 sera	++++	+++
2 sera	+++	+++
1 serum	±	neg.
1 serum	+++	++
3 sera	+	++
2 sera	+	neg.
1 serum	neg.	±
4 sera	neg.	neg.
(the above was termed agreement)		
2 sera	++	neg.
2 sera	++++	+
1 serum	+++	+
1 serum	+++	±
5 sera	++	++++
1 serum	++++	++
1 serum	++++	neg.
1 serum	±	++++
2 sera	neg.	++++
1 serum	±	+++
(This was termed disagreement)		

The sera from the syphilitics was always one day older when tested than that from the new admissions. Whether the age of the serum makes the Kahn test weaker we do not know. We had two sera from cases not under arsphenamine treatment which when fresh and first tested gave both ++++ Kahn and Wassermann tests. When these two samples were about a week old they gave weakly positive Kahn tests but still the ++++ Wassermanns. A serum from a third case gave ++++ Wassermann and Kahn tests when tested on two successive weeks. Then for two successive weeks later this same sample gave a ++++ Wassermann and negative Kahn test. When the fourth test was being made on this sample, a fresh sample from the same man, who had been started on arsphenamine treatment, was tested. The Wassermann with this fresh serum was ++, the Kahn test +.

TABLE II

Two Hundred and Thirty-eight Sera from New Admissions

	Kahn test	*Wassermann test*
14 sera	++++	++++
3 sera	++++	+++
1 serum	+++	++++
3 sera	+++	+++
6 sera	±	neg.
1 serum	neg.	+
203 sera	neg.	neg.
(the above was termed agreement)		
1 serum	+++	neg.
2 sera	++	neg.
1 serum	++	++++
1 serum	++++	++
1 serum	neg.	++++
	(test repeated with same result)	
1 serum	±	+++
(this was termed disagreement)		

One of the two sera in Table II in which the Kahn test was ++ and the Wassermann test was negative was from a man seventy-four years old. The diagnosis of his case was senile dementia. The serum in Table II showing a ± Kahn test and +++ Wassermann was from a case diagnosed dementia precox, catatonic type. The spinal fluid from this case gave a negative Wassermann. In the other cases of disagreement in Table II, the spinal fluids from the cases gave ++++ Wassermann tests and the diagnoses of the cases were all general paralysis or paresis.

Although we had some positive Kahn test reactions with the plain alcoholic antigen, they were not many and were weaker than the reactions with the cholesterinized antigen. The results with these are shown in Table III.

TABLE III

Kahn Test Results with Plain Alcoholic and Cholesterinized Antigens

	Plain Antigen	*Cholesterinized Antigen*
46 sera	neg.	++++
18 sera	neg.	+++
9 sera	neg.	++
4 sera	neg.	+
8 sera	neg.	±
1 serum	++++	++++
4 sera	+++	++++
12 sera	++	++++
6 sera	+	++++
1 serum	±	++++
3 sera	+	+++
1 serum	+	++
2 sera	±	±

Kahn tests were performed parallel with the Wassermann on 177 spinal fluids. The tests were performed in the same way as the serum tests except that .6 c. c. of spinal fluid was used. These also were from syphilitics and from new admissions at the hospital—in fact from some of the same people from whom the sera came. There was agreement between the results of the tests in 68.3 per cent. only. In the disagreements it was the Kahn test that was weaker or negative. We feel that a larger amount of spinal fluid should have been used in the tests. But we were limited in the amount of spinal fluid that we had and only rarely had enough to use larger amounts.

This work has convinced us that the Kahn test has great possibilities of being a simpler, more direct, more readily standardized method than the Wassermann test for serological diagnosis of syphilis. But we would want to see it more thoroughly worked out and tried, before we used it to replace a test as reliable as the Wassermann.

Urography*

By B. H. NICHOLS, M.D.,
Cleveland,
Cleveland Clinic.

Perhaps no field of röntgenology is receiving more attention at the present time than that of urography, and we believe justly so, for a great deal of information of a definite nature and of diagnostic importance may be obtained in this manner. Therefore a modern equipment for this work should be a part of the armamentarium of every well appointed röntgen laboratory.

The injection of the opaque solution bears the same relation to the study of the genitourinary tract that the opaque meal does to the study of the gastrointestinal tract, and we should, therefore, equip our x ray laboratories as thoroughly for this type of work as for gastrointestinal work. The difficulty of the technic of genitourinary investigation, however, is very great and requires the cooperation of a trained urologist. Fortunately, at the present time, there are many urologists who have had good training in the technic of diagnosis of the diseases of the genitourinary tract, and these men are almost invariably glad to cooperate with competent radiologists, either in the hospital or office laboratory. In a short time there will be on the market cystoscopic tables equipped with Bucky diaphragms and with all the x ray attachments essential for the making of urographs with a minimum of discomfort to the patient and a minimum consumption of time.

With the establishment of such a cooperation, it is evident that in most cases it will become the duty of the radiologist to determine what cases should be submitted to this type of examination, and what should be the definite procedure in each case. This brings us to the realization that the röntgenologist is not a technician, but a consultant in the broadest sense of the term and that, therefore, he should understand the terminology of lesions of the urinary tract and be thoroughly informed regarding the significance of the history, laboratory findings, and clinical picture of every case brought to him for examination.

The majority of cases with symptoms referable to the urinary tract are sent to the röntgenologist for an examination to determine the presence or absence of stones. But the referring doctor will be just as appreciative of a correct interpretation of whatever pathological condition in the genitourinary tract that may account for the patient's symptoms in a case in which no calculi are present as in a case in which stones are present. That is, a request for an x ray examination of this tract should be met exactly as a request for an examination of the gastrointestinal tract is met, i. e., by an exhaustive study to determine any pathological condition that may be present which is demonstrable by the x rays. The röntgenologist would hardly feel that he had rendered his best services to a patient with gastrointestinal symptoms, if he simply made x ray plates of the gallbladder and reported that no stones were seen in the gallbladder area but made no further investigation.

It is not, however, to be inferred from this that all genitourinary examinations should include the study of the tract by the injection of an opaque solution. For example, in considering cases which show suspicious shadows, the following must be ruled out as possible causes:—1, warts, scars, etc., on the surface of the body over the kidney area; 2, gallstones; 3, calcified glands; 4, calcified costal cartilage; 5, previous injection of opaque substance, as of bismuth, silver salts, or other solutions; 6, phleboliths;

---

*Read before the American Röntgen Ray Society, Louisville, Ky., February 24, 1923.

7, foreign bodies in the intestinal tract, compound cathartic pills, enteroliths, or retained barium, particularly in diverticuli; 8, inspissated pus in tubes.

These may seem to be outside the subject under discussion but is it not all important to determine exactly the cause of a suspicious shadow and its location? Certainly it is not desirable to submit a patient to a urographical examination when a suspicious shadow is seen on a röntgenogram if it can be determined that this shadow is due to a wart on the patient's body or possibly due to bismuth which the patient has been taking medicinally. In other words, a careful study of the case must be made by the easier methods in order to rule out all such possibilities as those listed above. Moreover, it is important to make at least two plates of the same area, thus ruling out artefacts in the plate itself.

Recently we had sent to us from New York for operation a patient who had with her x ray plates of the genitouninary tract which showed a suspicious shadow in the ureteral area. This case had been seen by two able men in New York, one a röntgenologist and the other a urologist, and both agreed that the shadow was that of a stone in the ureter. Only one plate of the ureter had been made, however. We reexamined the case and found nothing. By careful examination in the oblique position of the plates brought by the patient, we found that a small drop of solution had fallen on the plate just over the ureter and caused the mistaken diagnosis; this could not have occurred if two plates had been taken of the same area as in our routine procedure.

The röntgenologist should not be in a hurry to give an opinion. It should be borne in mind that the report from the röntgenologist as to the pathological findings will usually determine whether or not a surgical operation is necessary and that such an operation is usually a major one and of grave significance to the patient. The decision may well be delayed, therefore, for a reexamination of the patient at a later date may show that enteroliths or foreign bodies have changed their position thereby establishing their identity.

For differentiation between a gallstone and a kidney stone, stereoscopic plates should be made, and also a lateral plate, which will help to determine whether the shadow is posterior in the kidney area or anterior in the gallbladder area. We have recently been studying the stereoscopic plates with a localizing stereoscope which is of considerable aid. By this method in a case of a gallstone a plate in the gallbladder position should show the stone smaller, more distinct and close to the spine while a plate in the kidney position should show a shadow of larger size and of lesser density, and forced up under the ribs by the compression.

When all the simple procedures have been exhausted in an effort to determine the nature of a suspicious shadow, but without success, more elaborate methods must be used. In many cases of stone in the ureter, the opaque catheter will determine its location. However, this cannot be relied upon in every case and particularly in those cases in which the catheter does not come in contact with the shadow an ureterogram will have to be made.

A large, dilated ureter may have within it a stone which lies some distance from the catheter, or a tortuous ureter into which a catheter cannot be passed for its entire length may hold a calculus in one of its loops. In either of these cases the position of the stone can be determined only by a ureterogram.

By means of a pyelogram determining the location of the kidney pelvis, a suspicious shadow in the kidney area may be found to be a stone in the pelvis of the kidney or in the cortex, or the shadow may be found to lie outside the kidney. So also a cystogram will determine the presence of a calculus in the bladder or in a diverticulum, or localize the suspicious shadow outside the bladder area.

Thus far we have been discussing only those cases in which a suspicious shadow is found in the genitourinary area. These present comparatively simple problems.

The problems presented by another group of cases, those in which no suspicious shadows are seen, are not so simple and it is in this group that urography becomes the most valuable method of diagnosis. In these cases, the history, all the physical findings, the symptoms and both the chemical and the microscopical urinalysis must be carefully considered in determining what urographical procedure should be undertaken. As it would be impossible for me in the limited space at my disposal to describe all the methods which may be used in these cases we shall consider only a few of the most important, and in particular the indications for and the technic of making cystograms, ureterograms or pyelograms.

Every röntgenologist should be able to make a urinary cystograph, which can be done without the aid of an urologist. The technic is simple. First, with a sterile catheter, the bladder should be washed out with a sterile solution and then filled with a solution of sodium iodide, films being then made in the anterior posterior and in the lateral position. This should be done in cases in which the symptoms are those of a persistent cystitis with infection, in which no calculus can be found in the bladder. These cases give a history of long continued symptoms with little relief after medical treatment or irrigations. Many of them show a single diverticulum or multiple lesions of the bladder in which urine may be retained for long periods with resulting infection and diverticulitis.

Posterior diverticuli are sometimes seen only by a lateral exposure which should, therefore, always be made. The technic is not difficult and cases of this type should not be overlooked, as in many of them surgical treatment gives prompt and permanent relief from all symptoms.

As for the indication for making a ureterogram or a pyelogram, this may be determined by the history of the case. In cases with intermittent attacks of pain in the kidney and ureteral areas, with no evidence of calculus and in which gastric and duodenal ulcer and gallbladder disease have been ruled out, a careful study of the ureter and kidney pelvis on the affected side should be made to determine the presence of a possible intermittent hydronephrosis. We see many of these patients who have undergone operations on the gallbladder and appendix without relief. Intermittent hydronephrosis is quite frequently found and should be considered as a possibility, particularly when the symptoms indicate a pathological condition in the upper right quadrant.

Cases with persistent hematuria, in which no causative factor can be found in the bladder, often require consideration. The side to be examined or injected may be determined only after the insertion of the catheters in the ureters makes it possible for the separate specimens to show from which kidney the hemorrhage is coming. If, after the catheters have been introduced, one side drains with a constant flow unlike the interrupted flow of the urine from a normal kidney, a possible hydronephrosis is suggested and a urographical examination is indicated.

If the discharge of large quantities of pus from a ureter indicates a pyonephrosis, the diagnosis may often be confirmed by a pyelogram. By means of a pyelogram a tumor mass in either side may either be definitely diagnosed as a kidney lesion or be shown to bear no relation to the kidney. The displacement of a kidney may be definitely determined by a pyelogram of its pelvis. If a case with hematuria shows deformity of the kidney pelvis, the patient should always be questioned regarding the occurrence of trauma, as a blood clot in the kidney pelvis may give a shadow simulating a tumor of the kidney. In cases which show a large dilated kidney pelvis, after the catheter has been withdrawn, plates should be made with the patient in the upright position and without compression. These will often reveal that the obstruction is due to kinks in the ureter, whereas if the plates are taken with the catheter in place, the kinks may be straightened out and the cause of the obstruction will not be found.

The röntgenologist should become familiar with every phase of this work in order to render the best service to the referring physician and to his patient. In our laboratory the patient is examined in the urological section on a cystoscopic table into which a Potter-Bucky diaphragm has been incorporated. Films are first made with catheters in both ureters. Then the side we wish to examine is injected by the syringe method with a solution of sodium iodide until the patient feels a twinge of pain in the kidney region and films are made in the anterior posterior position with a soft rubber bag compression. The patient is then placed in the sitting posture and the catheter withdrawn to the lower end of the ureter. If necessary a small amount of the sodium iodide solution is then injected into the ureter; this is rarely required, however, as the ureter will be filled by the return of the solution from the kidney. In this latter position no compression is used and kinks of the ureter, as well as displacement by ptosis, may easily be shown.

The injection of an opaque solution into the genitourinary tract must be done only by one who is thoroughly familiar with the technic and aware of all the dangers with which it may be fraught. Catheters have been known to be inserted too far into the kidney pelvis, causing a loop with a knot in the end which required an operation for its removal. Danger of overdistention of the kidney pelvis and of the rapid absorption from the kidney pelvis as shown by a phenolsulphonephthalein injection into one pelvis and its recovery in a few minutes from the other kidney is to be borne in mind in urological examinations. Dr. Lower, who is the head of our section in urology, makes it a rule from which we seldom deviate, that only one side may be injected at a single examination. It is evident, as I have already stated, that the cooperation of a competent urologist is essential in this work.

I realize that I have touched upon only a few points in the application of urography to the diagnosis of lesions of the genitourinary tract; but, if we succeed in stimulating the study of this subject and the broader application of its principles, we shall feel amply repaid for our efforts.

Oral Infection in Relation to Health*

By MARTIN J. SYNNOTT, A.M., M.D., F.A.C.P.,
Montclair, New Jersey.

According to reliable vital statistics the average span of life in this country has been rising gradually since 1906. This gratifying state of affairs is due to many factors, among which may be mentioned improved economic and living conditions, a better knowledge of the principles underlying the conservation of child life, public health measures preventing and controlling epidemics, the more general understanding of the causes, prevention and treatment of metabolic disturbances, and finally the unqualified recognition by the medical profession of the importance of the focal infection theory.

It is with the last factor—focal infection—that we are concerned in this paper. If tumors, tuberculosis, traumatic injuries, glandular dystrophies, such as cretinism and acromegaly, syphilis, and the acute exanthemata are eliminated from consideration, we are at once impressed with the fact that almost all the conditions physicians are called upon to treat are the direct or indirect result of focal infection. Thus, heart disease, disturbances of the endocrine system, polyglandular insufficiency, diabetes, nephritis, various forms of mental deterioration, functional nervous disturbances, arthritis, secondary anemia, are almost always the end results of preexisting infections. If the infectious foci can be detected in time, before permanent damage has been done, as a result of the distribution through the body by way of the lymph and blood channels or by direct swallowing of bacteria and toxins, countless millions of people may be saved much suffering and the working power, efficiency and happiness of the race greatly increased.

The usual sequence of a chronic toxemia is as follows: a bacterial infection starting in teeth, gums, tonsils, or accessory sinuses; secondary foci in stom-

---

*Read at a meeting of the Orange Mountain Medical Society, Orange, New Jersey, June 15, 1923.

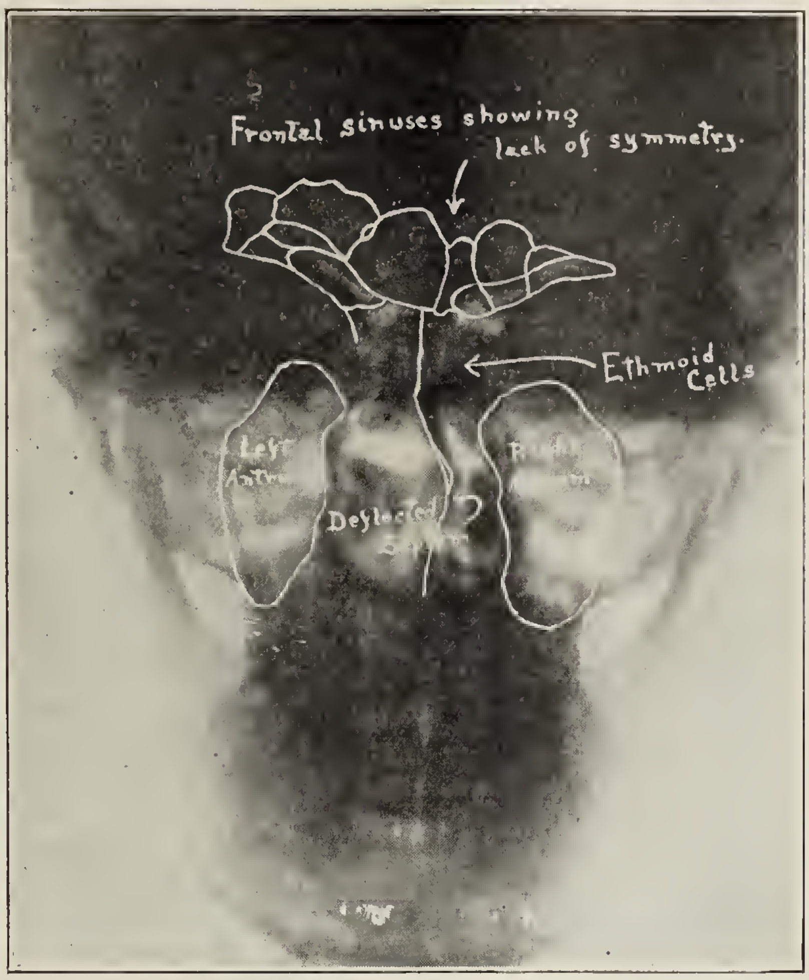

FIG. 1.—Rœntgenograph of head, showing lack of symmetry in frontal sinuses—a condition frequently met with—which demonstrates the unreliability of transillumination in diagnosing frontal sinus disease.

:h, duodenum, gallbladder, pancreas, or appen- x; following which we hd often a chronic mu- ous colitis, enlarged ediastinal glands, spas- : constipation, intesti- l stasis, chronic nephri- s, endocarditis, myo- rditis, nephritis, arthri- s, various psychoneu- ses, etc.

With a knowledge of is fact in mind, it is ap- rent at once that every tient who comes to us r advice about a ronic ailment is entitled at least one complete nd thorough physical rvey. The gastroin- stinal specialist who ndertakes to treat an fectious achylia gas- ica without examining e oral cavity for dis- sed teeth or tonsils, or e surgeon who operates r hemorrhoids without amining the patient for llbladder disease, or her trouble higher up in the alimentary canal, are the class with the internist who prescribes for a yocarditis or a nephritis without attempting to cate and eradicate the source of the toxin which s caused the heart or kidney disease.

It may be worth while mentioning at this point that ery patient should have a Wassermann blood test ne. It takes only a minute to obtain the speci- en, and a single positive case picked up in this ay, out of fifty or a hundred, will well repay e for the trouble and save unpleasant em- rrassment and discomfiture later on. Where philis is strongly suspected, a negative Was- rmann in the blood must not be taken as final. provocative salvarsan injection should be given d a series of blood Wassermann tests done every y or every second or third day for ten days there- ter. Many patients will require a spinal puncture, d a spinal fluid Wassermann, before syphilitic in- ction can be definitely ruled out.

After the survey, which should always include a mplete urine analysis, supplemented in certain ses by a blood count and blood chemistry, by an x y examination, by gastric analysis, by duodeno- liary drainage, by rectal or vaginal examination and stoscopy, the findings may be correlated and the ajor and minor foci of infection carefully noted fore deciding on a rational plan of treatment.

Much of the ridicule to which we medical men are bjected by the laity and the humorous writers in e press is due to our own hurried and superficial ethods of examining patients. Thus the physician ho when consulted by a sufferer from, let us say, iatica, looks into the mouth, and says without fur- er investigation, "Ah! here is your trouble! Have ose two goldcrowned roots removed and you will get well," may strike it happily in an occasional case, but there will be many instances where such extraction will accomplish no good, and he will be confronted by a disgruntled patient who will perhaps subsequently dissuade some friend or relative from having an oral infection treated where it is unquestionably indicated.

In studying our chronic cases we are often impressed with the fact that the primary focus is not always the major focus. Thus a careful study may reveal a chronic cholecystitis of low grade infective virulence, with perhaps in addition a chronic mucous colitis or spastic constipation as the major focus, although this condition has resulted from a bacterial infection starting in the teeth or tonsils. It will readily be seen that advising such an individual to have infected teeth or tonsils removed without attempting to treat the gallbladder or colon condition is very apt to lead to therapeutic disaster or disappointment. Likewise, it is well to bear in mind that headaches may be due to a nephritis, intestinal toxemia or arteriosclerosis, as well as to infected antra and frontal sinuses; joint involvements may be due to a gouty diathesis, syphilis, gonorrhea or tuberculosis; a neuritis in the obese individual with low blood pressure, to potential diabetes (Allen), detected only by a blood sugar determination; the pains in the shoulders and arms to degenerative changes in the aortic arch; or the clinical symptoms may come from an infected cervix, prostate, seminal vesicles, or tubal disease.

With this knowledge constantly in mind we will not be led into the all too common error of urging the reckless extraction of teeth first and then, if the patient fails to improve, studying him further to find out what really ails him.

We must not be misunderstood as opposed to the removal of diseased teeth or tonsils. On the contrary, we believe in the most radical efforts at removal of all oral infection. But we wish to emphasize the importance of thoroughness in the examination of our patients and candidness with them, otherwise we shall surely bring our art into disrepute. The patient who comes to us for help, and is found to be a victim of multiple infectious foci—teeth, tonsils, achylia gastrica, duodenitis, biliary stasis, a nonfunctioning colon, chronic nephritis and myocarditis—should not be promised a cure after the removal of a few teeth. Such a patient should be allowed to see the cards face up on the table, and made to understand that the elimination of the oral infection is only one step in a general systemic cleaning up process. He or she should be made to understand that the diseased teeth constitute only one section—perhaps the least important—of the vicious circle. In other words, if the doctor does not promise too much, the patient will not expect too much, and will not be disappointed if no immediate improvement is noted. On the contrary the properly prepared patient gives us willing coöperation and follows our guidance cheerfully, instead of becoming a recruit in the ever increasing army of skeptics, therapeutic misanthropes, and discontents, who go from bad to worse and finally land in the hands of the "cultist" or "curist."

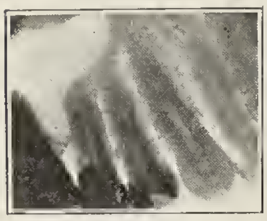

FIG. 2.—Upper jaw. Showing downward projection of antrum, a condition sometimes mistaken for alveolar abscess by inexperienced Roentgenologists.

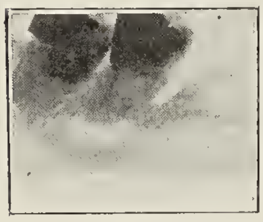
The physical survey should begin with a careful inspection of the oral cavity and accessory sinuses. The tonsils are first examined, and brought into view. The Hurd separator is a useful instrument for this purpose. By it the anterior pillar is hooked back, and the tonsil squeezed forward, when the crypts, if there are any, may be emptied of pus or serum, and cultures taken. Many tonsils, which appear quite normal on casual inspection, will show definite infection when examined in this manner.



Two methods of diagnosing sinus trouble are open to us—transillumination and the x ray. The former is valuable in examining the antra, but of doubtful use in examining the frontal sinuses, for the reason that these sinuses are rarely symmetrical, as the x ray films easily demonstrate (Fig. 1). The x ray is a sure, unfailing diagnostic aid in the examination of teeth and sinuses. The teeth should always be carefully inspected and if there are large fillings, discolorations, gold crowns, permanent bridge work or pyorrhea, a complete x ray examination is absolutely essential. We do this work ourselves, in our own x ray laboratory—for several reasons: it saves time for all concerned, and we believe the work can be done more satisfactorily in a general laboratory than in the specialized dental laboratory of the average oral surgeon. Furthermore, we now always include stereograms of the facial sinuses in all röntgen dental examinations, and the average dentist is lacking in the knowledge or equipment to do this work properly.

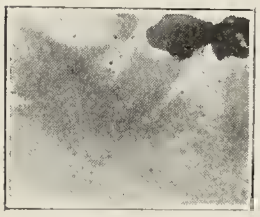


FIG. 3.—Lower jaw. Apical abscess extending into inferior dental canal.

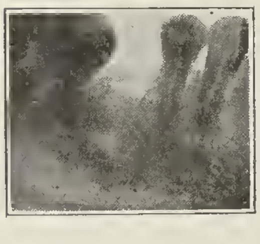

FIG. 4.—Lower jaw. Area of residual infection; osteomyelitis extending into inferior dental canal.

Every physician doing general diagnostic work must himself understand how to recognize x ray pathology in teeth or sinuses, and to interpret the significance of the röntgen findings, and thus avoid diagnostic errors. It has happened that downward projections of the antrum (Fig. 2) have been mistaken for abscesses and other equally serious errors have been made by men whose lack of experience in interpreting dental x ray films has led astray.

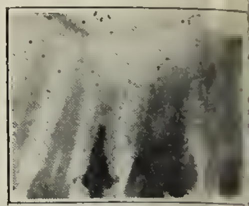

FIG. 5.—Upper jaw. Peridental membrane destroyed; infection extending through floor of antrum.

Impacted and unerupted wisdom teeth are a frequent cause of trouble, such teeth often showing coronal abscesses or other evidence of infection. The apical abscesses and granulomata, pyorrhea, sclerotic bone, osteoclasia, cysts caries, areas of residual infection, etc., are a few of the conditions most frequently met with and easy of recognition by the practised eye.

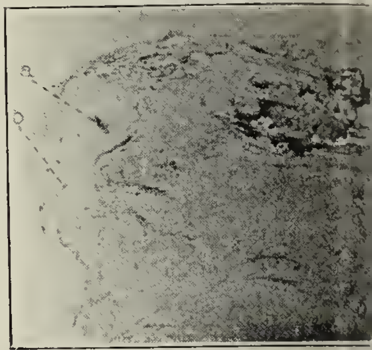

FIG. 6.—Section of granulom from apex of tooth. Low power. Note dark area "a" in center o blood vessel and lymph tract "b.

When we reflect on the bony anatomy of the mouth, it is easy to understand why diseased teeth so readily lead to systemic infection. On the lower jaw we have the inferior dental canal with its artery, vein, lymph channel and nerve. The apices of the teeth on the inferior maxilla are separated normally from this canal by only a thin partition of bone. When the lower teeth become diseased, and there is bone destruction from osteomyelitis and alveolar abscess (Figs. 3 and 4), the blood, lymph vessels, and nerve in the inferior dental canal are literally bathed in pus, with the result that microorganisms and bacterial poisons find an entry into the circulation and are carried to distant parts of the anatomy. Thus Rosenow has demonstrated that pyelitis and cystitis are often hematogenous infections from the teeth and that the end results of these diseases are frequently renal calculus and stone in the bladder.

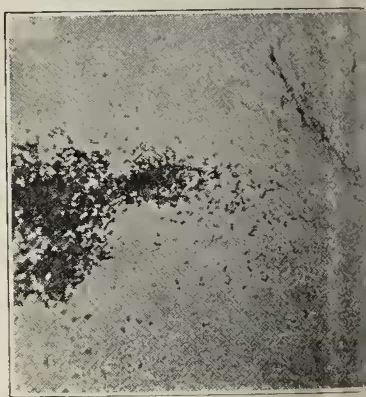

FIG. 7.—Cross section of da area "a" in previous Fig. 6. High power. Showing clump streptococci with microorganism invading adjacent tissue.

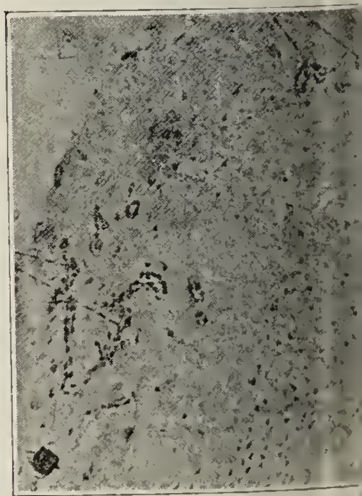

FIG. 8.—Section of granulom at apex of infected tooth, showi cross section of capillary e tirely occluded with streptococ and cross sections of capillar showing single layer of endothel cells.

On the upper jaw likewise, the lateral incisor, the cuspid, bicuspid, and first molar, are in close contact with the floor of the antrum. Infection at the apices of these teeth may and undoubtedly often does extend directly into the antrum (Fig. 5). It must be remembered that every time the jaws are rought together in mastication a pressure of from orty to sixty pounds is exerted. Pus pockets or ranulomata in the alveolar sockets of either upper r lower jaws, when subjected to such pressure, may asily exude toxins and even live bacteria into the djacent tissues, blood and lymph vessels (Figs. 6, 7, and 8).

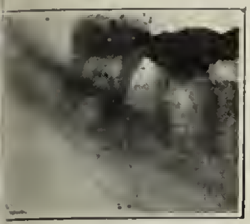

Fig. 9.—Lower jaw. 'artially filled root anals; devitalized ooth without definite oentgen pathology.

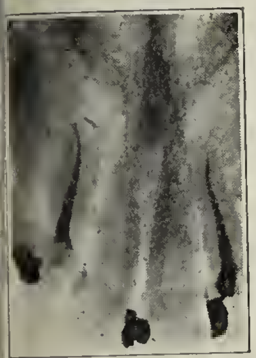
Antrum infections are often overlooked, as they rarely give local symptoms of pain or tenderness. There may be a chronic rhinitis, enlarged middle turbinate or mucopurulent discharge into the nasopharynx. The symptoms are more often those of a chronic toxemia. Functional psychic phenomena are common. I recall the case of a recent patient, a lady of forty-five, who had a delusion of ersecution by the Ku Klux Klan. We made a öntgen diagnosis of a right antrum infection, and operated, although no symptoms directly referable to the antrum were observed. When it was opened the cavity was found to be filled with necrotic tissue, polyps, and bone caries, the curettings being so malodorous that the windows of the operating room had to be opened.



Edema of the lower eyelids—which we were taught as medical students to regard as a symptom of Bright's disease—is in my opinion frequently an indication of chronic antrum or ethmoid infection.

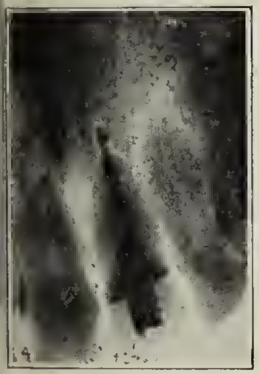


Fig. 10.—Upper jaw. Completely filled root canals; no definite röntgen evidence of infection.

The most brilliant results in the annals of medicine and surgery have followed the removal of infected teeth, tonsils and the opening, curettage and drainage of diseased sinuses. Obstinate facial neuralgia, various forms of neuritis, tinnitus aurium, chronic suppurative otitis media, iritis, recurring furunculosis, malignant endocarditis, digestive disturbances, particularly infectious achylia gastrica, chronic pyelitis, rheumatic fever, arthritis and a long list of other ailments have over and over again been cured by oral surgery. Enlarged cervical glands, all varieties of headache, chronic endocarditis, symptoms of nephritis and myocarditis, metabolic disturbances, among which we desire to mention prominently hyperthyroidism, have been known to disappear or have been greatly relieved by the removal of infected tonsils or teeth.

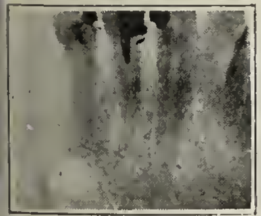

Fig. 11.—Lower jaw. Cyst formation resulting from residual infection.

While it is unquestionably wrong to advise patients suffering from chronic ailments to have all their teeth removed without even a röntgen diagnosis, as is frequently done by certain overzealous physicians nowadays, the writer is firmly of the opinion that all teeth showing gross apical pathology and plainly evident alveolar infection or general pyorrhea should be removed. But teeth which are vital and useful for reconstruction purposes should never be needlessly sacrificed.

The x ray frequently shows pulpless teeth with partially or completely filled root canals but without definite röntgen evidence of apical infection (Figs. 9 and 10). Should such teeth be extracted? This is a mooted question. There are the radical physicians and dentists who maintain that all pulpless teeth are infected and should therefore be removed. There are others who assert that not all pulpless or devitalized teeth are dead, and these men advise leaving such teeth alone, particularly if the röntgen film shows the presence of an intact peridental membrane. Still others—the ultraconservatives—believe that a tooth should be saved at any risk. What is the correct solution? Unfortunately, there are no hard and fast rules to guide us. In deciding whether or not devitalized or pulpless teeth, which show no visible röntgen apical infection, are to be removed, I believe we should be conservative at least in selected cases, until it can be proved definitely that all such teeth are infected. This opinion might of course be modified in the case of a sufferer from a chronic progressive ailment like arthritis, if a most exhaustive search failed to find any other possible focus. In such a case both physician and patient would, it seems to me, be justified in taking a gambler's chance and sacrificing one or more dead teeth even though the röntgen films showed nothing more serious than absence of vitality. The patient should, however, be told frankly that the extraction is largely experimental, but justified by the seriousness of the outlook. Occasionally a long shot of this kind hits the bull's eye.

All dental extracting should be done by a skillful oral surgeon who operates in the modern way, with the minimum of trauma. The alveolar cavity must be cleaned out and all necrotic tissue removed by careful curettage, as otherwise an infected process may be left behind to give trouble in the future. It is not an uncommon experience to meet cases where the gum has healed over after extraction and looks quite normal, but the röntgen film reveals distinct areas of residual infection (Fig. 4), or of cystic degeneration (Fig. 11). This is often seen in many edentulous jaws. After extracting teeth, the importance of early restoration of the patient's masticating efficiency should be borne in mind.

Since it is conceded that oral infection, particularly dental pathology, is such a prolific source of disease and suffering, the importance of proper prophylactic care of the teeth and mouth cannot be overestimated. This must begin in infancy with proper feeding, because it is a well known fact that malnutrition and varying degrees of rickets and scurvy cause faulty development of the jaws and the bones of the face, with resultant irregular teeth and poor occlusion.

The first or temporary teeth require just as much care as the permanent ones. Formerly, mothers were told by their dentists and physicians to pay no attention to decay in the temporary teeth. It was said that these first teeth must be retained at all hazards, as their removal would affect the growth of the jaws, the permanent teeth would be crowded and overlap, faulty occlusion would result and the child's beauty be permanently marred. This advice was bad. Decay in the temporary teeth should be prevented by proper feeding and proper cleansing and if found to exist treated just as thoroughly and radically in a child as in an adult. Regular dental inspections of a child's mouth are of utmost importance.

Acids forming in the mouth from decomposing food cause decalcification of the teeth, caries and cavity formation. If the caries extend into the pulp of the tooth it means toothache, infection of the nerve and death of the tooth. Such acid formation—usually lactic acid—results from carbohydrate food fermentation. The germs always present in the mouth act on the carbohydrate food, i. e., sweets, candies, jams, jellies, sugars and starches, if it is allowed to remain on or between or about the teeth and cause the formation of the corrosive lactic acid. Soft, sticky, carbohydrate foods, such as candy and sweets, should therefore be eliminated as much as possible from the child's diet.

Nature's method of preventing caries lies in the saliva, whose ferment, ptyalin, has the property of digesting and dissolving carbohydrates, and whose alkalinity neutralizes harmful acids. Saliva is therefore the best mouth wash, and its free flow should be stimulated by giving food which requires thorough chewing, and acid fruits such as oranges and apples. I believe that the ptyalin of the saliva is not there to aid gastric digestion but to protect the teeth.

In cleansing the teeth, ordinary brushing is not enough. Dental floss must be used to remove particles from between the teeth and the tooth brush must be made to move up and down as well as across the teeth. Care must be observed not to treat the mouth roughly, or to bruise or traumatize the gums in cleansing the teeth with too stiff a brush. Too vigorous brushing may cause the gums to recede from the teeth and thus cause pyorrhea, with pus pocket formations, later in life.

Prompt dental intervention should be advised whenever decay is detected in a child's teeth, because infected material from the oral cavity, as previously pointed out, may be swallowed with the food or saliva, or the bacteria and their toxic products may enter the blood or lymph streams and be carried throughout the body, thus laying the foundation for much subsequent ill health. Vital teeth should be carefully filled but one should not hesitate to advise the extraction of a dead tooth even in a very young child.

Irregular teeth are more likely to collect food and are therefore more prone to decay. Faulty occlusion causes undue trauma on certain teeth, which predisposes to infection and makes proper mastication difficult. Where such irregularity of teeth and faulty occlusion are observed, proper correction by a good orthodontal surgeon should be sought. Modern dentistry works miracles in the alleviation of such conditions.

The wise doctors and the wise oral surgeons of the future will be the ones who endeavor by advice and counsel to prevent pathological lesions. To do this they must have minds ready and willing to grasp promptly the accepted facts of experimental physiology, and to educate the public to recognize the practical application of proved physiological principles. The best means of conserving health is by assisting nature to help herself.

Medical and dental cooperation is essential, if progress along these lines is to be made. Unfortunately certain members of the dental profession are averse to receiving any suggestions from physicians and regard advice on dental matters from medical sources almost as a personal affront, even where the röntgen evidence of advanced oral infection is so pronounced as to be beyond controversy. This spirit is gradually dying out, and most physicians and dentists are now very generally recognizing the principle that the interests of the patient must be paramount to all other considerations.

Figs. 6, 7 and 8 have been reproduced, with the author's permission, from an article entitled "Studies on Elective Localization: Focal Infection with Special Reference to Oral Sepsis," by Dr. E. C. Rosenow. *Journal of Dental Research.* Vol. I, No. 3, September, 1919.

Death by Electricity

By A. H. WERNER, M.D.,

New York.

On the first of March I watched for the first time an execution by electricity, and I satisfied myself that the death sentence carried out by this method was the most humane. Incidentally, I carried out the first step in my research regarding the destruction by electricity of the incitants causing infectious disease. The inoculation of two blood serum-agar tubes remained perfectly sterile. No growth could be detected after incubation for forty-eight hours at a temperature of 37.5° C. If Mr. Ogle, as he has stated to me, can construct an apparatus with which it will be possible to destroy all bacteria in vivo without destroying or injuring the human cell, it will revolutionize the treatment of all infectious diseases, as well as those which are caused by an intermediate host, such as malaria, yellow fever, and sleeping sickness. I cannot imagine that Mr. Ogle, who holds the position of chief electroengineer of the General Electric Company, would make such a statement rashly or without foundation, and I will say here that the profound knowledge which he possesses regarding electricity induced me to take up this matter and, if possible, to carry it to a successful termination regardless of time or expense.

Mr. Ogle has proved to me that he can destroy by electricity in the test tube two of the most destructive incitants, viz., the tubercle bacilli and the spirochæta pallida. The former entirely shrivels up and can only be recognized microscopically because it retains its power to retain the carbol-fuchsin stain;

the luetic spirillum (syphilitic virus) is breaking into several pieces under the influence of the electric current, and therefore we can safely assume that it also has been destroyed. Should electric sterilization of the living incitants in the human body become a fact it would be of great benefit to humanity. Millions of lives would be saved annually and the dread of tuberculosis, cancer and syphilis, which take the greatest toll of human life, would be at an end.

Let me give my impressions with regard to electrical death. In all the medical literature I have never come across a scientific explanation as to the actual cause of death, and I do not assert that my impressions are conclusive, because it is impossible to observe all the physiological phenomena which present themselves in such a short time. The face being covered down to the mouth in electrical execution deprives one of the study of the facial expressions in the moment the electric contact is applied. I will divide my observations into two groups: first, during electrocution and, second, during autopsy.

The person I saw who was to be executed was quite composed, going to take his seat in the fatal chair with a calmness and composure which another person may not even show when sitting down to a dinner at a banquet table. Therefore my observations were not in any way obscured by any unpleasant incidents as otherwise would have been the case.

In bidding everybody goodby the man sat down into the fatal chair, was strapped down, the electrodes fastened to the right leg just above the calf of the lower extremity, and the other to the head in the form of a cap. All this happened simultaneously and occurred in less time than I can describe it. The moment these preparations were ended, and at the end of an expiration, the signal was given to the executioner, and the electric contact was made. I could not notice any distortion of the lower part of the face. The arms and hands which had laid upon the chair rests were turned inside and the hands closed with a jerk and kept close and tense, the thorax was compressed and held like in a vise, and the diaphragm was drawn up to the limit, so that the residuary air in the lungs was forced out with a hiss, like an explosive expiration. The legs became tense, the body was slightly raised as far as the straps would permit and bent backward. The body was held in this position until the current was released, when it slumped down into the chair. On examination by the prison physician, Dr. Squires found the heart fibrillating and the carotid arteries still pulsating, indicating that a second shock would be required. At this stage a severe cyanosis had already set in.

During the second shock the same phenomena could be observed, with the exception that the hands, which up to that moment had been firmly closed, opened and were extended with full force to the utmost. An air bubble was formed in front of the mouth, showing that the air which had reentered the lungs after the current had been shut off was again expelled by the contraction of the whole respiratory mechanism. After about five seconds the current was again cut off. The body became limp, except for the right leg, which was already in rigor mortis. Another examination proved *exitus letalis* and Dr. Squires pronounced the man dead, after which the corpse was immediately removed to the autopsy room.

After the corpse had been stripped I made a general inspection and was surprised to find no burn on the head where the electrode had had contact with the scalp, but a second degree burn on the right leg where electric contact had been made. This burn was quite extensive and was as large in area as the size of the electrode. The corpse was that of an athlete, wellnourished and of strong muscular development. The man was an ex-veteran with a remarkable military record and his physical development was probably due to his military training. The region of the abdomen, the sexual organs and thighs were covered with a heavy growth of hair, which from our knowledge of endocrine function would prove a hyperactivity of the pituitary gland, and which would also account for the act of violence the man committed and for which he had just paid the penalty. Accordingly, the organs of reproduction were more than well developed. This type of man was the antithesis to the type of man suffering from a condition which is known as acromegaly, which is due to a pathological condition of the pituitary body. The body temperature was high above normal and this was especially marked in the right leg and proved to be 120° F. I was informed by Dr. Squires that the temperature in the brain amounted to 138° F. and over, with a slight decrease in the lungs, abdomen and pelvis. The face did not show any muscular distortion. The right leg was held as stated already in rigor mortis at an angle of 45° and the position could not be changed no matter how much force I used. The muscles and tendons were hard in contrast to the rest of the corpse which was limp and not at all affected by rigor mortis. A surprising phenomenon was the abnormal softness and pliability of the finger nails as well as the nails of the toes. After the opening of the thorax and the removal of the sternum, it was found that the left lung and pleura were strongly adherent to the thoracic wall. The adhesions were so strong that it was impossible to break them with the bare hands. A veritable wall of fibrosis had been formed. The surface of the lung on the right side appeared to be of a much darker color than normal and bled profusely when cut into; the smaller bronchi were filled with blood. This man had been shot through the left lung and gassed and therefore I cannot say apart from the fibrosis which changes were due to the electric current or to the gassing and wounding.

The pericardium externally showed nothing abnormal. On opening the pericardial sac, the heart was found to be in diastole, and I was told by Dr. Squires that this was not always the case; in others the heart was found to be in systole. The reason for this can only lay in the fact that electric contact is made just at the moment when the heart was either in one or the other position. On removal of the heart the contained blood therein nearly filled the thoracic cavity, the lungs having been left in situ. The heart itself appeared flabby and not of good muscular tone. The coronary arteries were still distended but no other external sign of degeneration could be detected. In opening the heart, the left ventricle and auricle proved the mitral as well as the aortic valves intact. There was only a slight difference between the walls of the left and right ventricle. On stimulating the cut surface of the heart muscle, nervous reflexes could be observed in the heart by muscular contraction.

This reminded me of an experiment which I made with a human heart after an execution (decapitation) in Germany; placing the heart in a jar of a warm physiological saline solution, the heart so removed from the body kept on beating for over an hour with the same rhythm and alternate action as shown in life. The abdominal organs were found to be normal with the exception of an intense hyperemia, even the mesentery was strongly injected. The organs, except for the spleen, were left in situ. The blood did not coagulate and I was informed that electric shock causes complete hemolysis (destruction) of the red and white blood cells alike. In the meantime, the cranial cavity had been opened and the brain removed; however, not before I had had an opportunity to see that there was a strong hyperemia and that minute hemorrhages had occurred over the whole surface of the brain. The pituitary body was removed and showed no abnormalities. On inspecting the brain we found in the left frontal lobe of the cerebrum an old lesion and slight atrophy probably the results of a pachymeningitis. The brain was steaming hot and the temperature of this organ taken previously revealed it to be not less than 145° F. This must be due to the fact that the brain, as the central organ of the general nervous system, receives the greatest force of the electric shock. The autopsy, which is made simply to comply with the law, was herewith ended, and the body left with the attendants to prepare it for burial.

CONCLUSIONS.

If there must be capital punishment—to which I am strongly opposed for the reason that it is not a deterrent to murder and crime and that as a physician it is my duty and profession to save and preserve life and not to destroy it—let it be by electricity, because, as I have already stated, it is the most humane.

The destructive changes in the body together with the development of the extreme temperature I am satisfied cause instantaneous unconsciousness and death. Death is caused by motor and respiratory paralysis and the extreme high temperature due to electric resistance. The fibrillation (flutter) of the heart after the first shock are simply nervous reflexes, and therefore a revival of an electrocuted person is impossible.

However, the greatest value lies in the discovery of the fact that all bacteria in the body after execution by electricity are destroyed and if we can construct an electric apparatus which will sterilize a man suffering from any disease caused by parasites without injuring the human cell, the greatest discovery in medical science will have been accomplished.

Subcutaneous Visceral Injuries

By HERMAN B. SCHOENBERG, M.D, F.A.C.S.,
New York.

Subcutaneous visceral injuries are not common, yet they are sufficiently frequent and serious enough to merit the most respectful consideration. They are of especial interest to the surgeon, because not infrequently the intestines may be ruptured and the injury fatal, unless operation is performed immediately. Unfortunately, there is no symptom or group of symptoms which can be said to be pathognomonic of visceral injury, yet there are some important differential points which, when properly elicited and assembled in the same case, may lead to a fairly accurate diagnosis.

The gravity of this condition can best be appreciated by a perusal of the mortality statistics reported in the literature. Schmitt (1) finds a mortality of 97.5 per cent. has followed expectant treatment. On the other hand, operation especially early operation, has greatly reduced this mortality, for although every patient with an internal injury is gravely ill from the beginning, yet in most instances is a good surgical hazard. Temporizing measures for the purpose of more accurate diagnosis and localization are inexcusable as the resistance of the individual diminishes with every hour of delay, and the only hope of the patient withstanding any operative procedure is to begin it before he is overwhelmed by a spreading peritonitis. Petry (2) presents a table of forty-two operative cases with a mortality of 67.7 per cent. Lund (3) reports fifteen cases with seven recoveries. Of those who recovered, all were operated upon. Kirstein (4) reports eighteen cases with an operative mortality of 55.5 per cent. Gage (5) reports twenty-nine cases in which operation was performed in the first twenty-four hours, with thirteen recoveries. Of those patients operated upon in the first four or five hours, nearly all recover. The reported mortality of patients operated upon in the first twenty-four hours is forty-five per cent.

Despite the great number of contributions on this subject urging early operation, the following statement appeared in a recent article on this subject by a surgeon of wide experience reporting a case of subcutaneous injury:

"The question of internal injury was carefully considered but with so little shock and no evidence of hemorrhage it was considered best to watch carefully the symptoms before making an exploration." This attitude of watchful waiting in this class of cases for more characteristic symptoms is shared by quite a number of socalled conservative surgeons. Brewer says, "To delay exploration for more characteristic symptoms is to invite disaster."

The usual agents of violence in the production of these injuries are either blunt forces, such as horse kicks, blows from fragments of wood thrown by circular saws, blows from wagon poles and fists, or compression forces, such as the passage of a vehicle over the abdomen. Violence applied to the lower abdomen is more likely to produce visceral lesions than when applied to the upper abdomen, for obvious reasons. The subjacent viscera are damaged by these agents either through direct compression of the organ between the vulnerating force and some bony point, such as the spine or ileum, or, as in the case of hollow viscera, by bursting from within. In compression injuries of the gut, the tears may be complete or incomplete, are usually single, and are to be found underneath the point at which the violence was applied; whereas, in bursting injuries of the intestine, the perforations are usually complete, multiple, and may be situated at a distance from that point.

There are two important factors which determine whether a subcutaneous injury will occur. First, the condition of the abdominal wall—whether thin or muscular, tense or relaxed. A blow received on a tense, expectant muscular abdomen will result most frequently in damage to the abdominal wall alone, producing either abrasions of the skin, ecchymoses, hematoma, or even rupture of the muscles. The viscera will escape in the majority of instances, whereas the same violence applied to a lax abdomen will almost invariably spell disaster for the underlying organs. Second, the condition of the viscera, whether distended or collapsed or, as in the case of the solid organs, the absence or presence of congestion. A stomach or intestine distended with food or gas, or the bladder distended with urine, is more likely to rupture than if empty. An enlarged, congested spleen or a congested, fatty liver is more commonly injured than a normal one. The viscus most often injured is the small intestine—in order of frequency, upper jejunum, terminal ileum and duodenum, because these portions are relatively fixed and for the same reason the cecum and ascending colon are the portions of the large intestine commonly involved. The tears in the intestine are usually located opposite the mesenteric attachment. There may be tears of the mesentery with either free hemorrhage or thrombosis. In injuries to the mesentery of the small intestine, it is well to note the exact location of the damage before deciding upon resection, because of the peculiar anatomical arrangement of the blood supply of the last twelve to fourteen inches of the ileum. Here the vasa intestini tenuis anastomose with the terminal branches of the ileocolic artery, and when the mesentery is injured at this location, it is unnecessary to resect because of this abundant blood supply. This point is illustrated in one of the case reports. The bladder may be torn intraperitoneally or extraperitoneally, and where the injury is due to a crushing force it may be torn in both directions, and is usually accompanied by fracture of the pelvis and may later give rise to extravasation and suppuration. The gallbladder is rarely injured. Of the solid organs, the liver and spleen are more frequently damaged than the kidney or pancreas and they often give rise to severe and at times fatal hemorrhage. Injury to the kidney and pancreas results in retroperitoneal hematoma and later in perirenal suppuration in the case of the former and fat necrosis and cyst formation in the latter. Injuries to the hollow viscera are more amenable to treatment and recovery occurs more frequently than from injuries to the solid organs, because of the severe hemorrhage which usually accompanies the latter.

SYMPTOMS AND SIGNS.

Shock.—In this class of cases shock is not a prominent symptom. In eighty-five cases collected by Gage, it was present thirty-six times. When present, it is trivial and transitory unless the abdominal injury is accompanied by other conditions, such as fracture or severe hemorrhage. Injuries of the upper abdomen show more shock because of the greater hemorrhage which is usually present in these cases. The amount of shock exhibited will depend also upon the temperament of the individual. A nervous, high strung person will exhibit more shock in the presence of a minor injury than will a phlegmatic person who has really suffered a serious one. I recently saw this point well demonstrated. A man who by the proverbial hair escaped being struck by a falling piano showed all the signs of severe shock, viz., cold perspiration, cold extremities, imperceptible pulse, etc., while his less fortunate companion, who was struck by the piano, receiving a crushing fracture of the leg, displayed none at all. According to Keen, even death may occur from shock following a simple contusion of the abdominal wall without any subcutaneous injury.

Pain.—Pain is always present. It is deep seated and is usually accompanied by an anxious, searching facial expression. It is diffuse and radiating.

Vomiting.—Initial vomiting almost always occurs and is of no diagnostic importance, but when it recurs and is persistent, it becomes of differential value.

Tenderness.—Tenderness is invariably present and like pain is deep seated and diffuse.

Rigidity.—Muscular spasm is a most valuable sign of subcutaneous injury. It is present from the outset and is not localized but rather diffuse and gradually increases in proportion to the amount of pressure applied to the abdomen until it becomes absolutely boardlike in character.

Tympany.—This is a late symptom of visceral injury, as is also the absence of liver dullness or the presence of fluid in the flanks. To wait for these signs is a loss of valuable time.

Pulse.—The pulse rate is at first rapid and after reaction becomes slow. An increasing pulse rate is significant of intraabdominal mischief and should be taken at half hour intervals to be of value.

Temperature.—This is of no diagnostic value; at first subnormal, it rises with the onset of peritonitis.

Respiration.—It is usually rapid, shallow, short and distinctly thoracic.

External signs.—There may be signs of trauma to the abdominal wall, such as abrasions, ecchymosis, hematoma, or even avulsion of the abdominal muscles. These are rarely present. The amount of visible damage to the abdominal wall is inversely proportional to the amount of visceral involvement in the great majority of cases. Again, the amount of violence exercised bears no definite ratio to the amount of injury done. Many observers have stressed this point. Eisendrath (6) reports a case of abdominal contusion in which there was a laceration of all the muscles of the abdomen, the muscles being torn away from the iliac crest, resulting in hernia in Petit's triangle without the slightest visceral damage.

None of the foregoing symptoms or signs or any combination of them is absolutely pathognomonic. The chief danger lies in mistaking a visceral injury for a simple abdominal contusion. There are, however, some important differential points which when properly elicited and interpreted are of the greatest value in establishing a diagnosis. Where the injury is limited to the abdominal wall, the pain is superficial and localized to the point of impact of the applied force and is unaccompanied by the characteristic facial expression of visceral involvement. Tenderness is likewise more superficial and localized and is a vastly more prominent symptom in this condition. The patient is literally afraid to have you touch his abdomen. Rigidity is also localized to the traumatized area and is voluntary in character, diminishing in proportion to the increased amount of pressure applied. In contusions of the abdominal wall *per se,* the amount of tenderness by far overshadows the degree of rigidity, whereas in visceral lesions the reverse usually holds true. In this class of cases, the external signs are as a rule very prominent and one may almost axiomatically conclude that the more the abdominal wall is damaged, the less are the subjacent parts.

The cases, whose histories are presented below, came under my care between January, 1915, and December, 1921, and are illustrative of some of the points made in this paper. In all these cases the injury was produced in the same manner, viz., by a piece of board thrown back by a circular saw.

Case I.—A. O., a strong man, aged forty, was feeding a board twelve inches long, four inches wide, and a half inch thick to a rapidly revolving circular saw, standing presumably with his abdominal wall relaxed against the end of the table. Suddenly the saw jammed and the board was slid along the table with great velocity against his abdomen. This occurred at 9 a. m. He fell down, groaned with pain, and in a few minutes was able to get up. He was admitted to the Polyclinic Hospital at about 10 o'clock. On admission he complained of severe pain over the right rectus at the level of the umbilicus. He said the pain was deep and boring and radiated to the back. There was no evidence of shock. He had vomited before arriving at the hospital. There was some tenderness over the lower right quadrant and marked rigidity over the same area. Pulse and temperature were normal, respirations were distinctly thoracic. There was not the slightest visible sign to indicate the point at which the force was applied. He voided clear urine. Operation was offered but the patient refused. When seen again at 12 o'clock, he felt much better, but seemed anxious. The pain was not quite so severe. There was moderate tenderness, but rigidity was absolutely boardlike. At this time he again refused operation, but the condition was explained to his wife and the gravity of delay was impressed upon her and finally, after three hours of persuasion on her part, he consented to operation.

Operation.—At 3:30 p. m., six and a half hours after the injury, operation was performed. An incision over the point of maximum rigidity revealed an abdomen containing blood and intestinal contents. Five small perforations were found in the ileum along the free border and these were turned in. There was also a large rent in the mesentery of the ileum higher up which necessitated resection of about eight inches of the gut with an end to end anastomosis with sutures. The peritoneal cavity was sponged out and drainage inserted. This patient made an uneventful recovery.

Case II.—L. D., male, aged thirty-five years, was struck in the abdomen over the right rectus about a finger's breadth above the level of the umbilicus. This occurred at 11 a. m. and the patient was promptly brought to the Polyclinic Hospital. On admission there were no signs of shock, but he complained of severe pain in the abdomen over McBurney's point which was deep and boring, radiating to the right lumbar region. He had not vomited. Palpation revealed a moderate degree of tenderness over the entire lower right quadrant but marked rigidity over the same area. There was a slight abrasion of the skin at the point where the force was applied. Pulse and temperature and respirations were normal. He voided clear urine.

Operation.—At 1:30 p. m., two and a half hours after the injury, the abdomen was opened and a large retroperitoneal hematura which pushed the cecum forward and inward was found. The parietal peritoneum was incised and the cecum displaced mesially and about two pints of clotted blood were evacuated. The right kidney was pulled down into view and was found to be almost completely bisected, the laceration extending from the outer border to the pelvis. This was sutured and the kidney replaced. Drainage was instituted through a stab wound in the loin and the parietal peritoneum closed. The abdominal incision was closed in the usual manner after carefully examining the intestines which were found to be uninjured. It is interesting to note that although the trauma was applied to the anterior abdominal wall, the only organ damaged was the kidney, the overlying intestine escaping.

Case III.—P. K., male, aged forty years, was injured about 10:30 a. m. and admitted to the Polyclinic Hospital about 11 a. m. On admission there were no signs of shock, but the patient complained of severe pain in right lower quadrant of abdomen, radiating to the back. He had not vomited, and there were no visible signs of injury to the abdominal wall. Palpation elicited tenderness over the entire abdomen, which was moderately distended, and marked rigidity over the lower half of the right rectus. Pulse and temperature were normal, but respirations were short, rapid and thoracic. The patient was distinctly anxious about his condition.

Operation.—At 2 p. m., three and a half hours after injury, operation revealed four small perforations in the ileum along its free border which were turned in. The mesentery of the terminal ileum at about eight to ten inches from the ileocecal valve had a circular tear about the size of a silver dollar. Because of the arrangement of the blood supply to this portion of the intestine, the gut was not resected but the tear in the mesentery was simply sutured and drainage was inserted. This patient likewise made a complete recovery.

Case IV.—C. L., male, forty years old, was struck in the abdomen about a finger's breadth below the level of the umbilicus. He was brought to the Polyclinic Hospital within a half hour of the occurrence of the accident. He exhibited no signs of shock, but complained of severe pain in the abdomen in the region of the umbilicus, radiating back to the spine. There was diffuse tenderness over the entire lower abdomen and marked rigidity over the same area. The patient vomited once, about an hour after admission, and appeared very anxious. Pulse and temperature were normal, respirations short, rapid and thoracic. He voided clear urine. There were no external signs of violence, except a very small streak of redness about two inches long below the umbilicus which indicated the site at which the force was expended.

Operation.—Three hours after admission, the abdomen was opened in the median line below the umbilicus and at first it appeared as though everything was normal but upon more careful examination a loop of ileum about four inches long was found contused with two small perforations opposite the mesenteric border. These were turned in and a drain inserted into the pelvis. This patient made a complete recovery.

Case V.—H. H., male, aged forty-five, was injured about 11 a. m. and admitted to the Community Hospital about 12 o'clock noon. When first seen this patient exhibited a mild degree of shock. He complained of severe pain, boring in character, in the region of the umbilicus, which radiated toward the back and down to the right iliac fossa. Shortly after admission he vomited, after which he reacted from his mild shock. There were no visible signs of injury and palpation elicited tenderness over the entire epigastric, umbilical and right iliac regions. There was marked rigidity over the same areas. Pulse was 70, temperature 97.6°, respirations short, frequent and thoracic. He voided clear urine. This patient appeared very anxious about his condition, but in spite of that refused operation at this time. When seen again at 2:30 p. m. he felt much better, pain was not so severe, vomiting had not recurred, tenderness and rigidity were still present and even more marked. He still refused operation. At 6 p. m. vomiting recurred and became persistent causing considerable distress. This continued until about 7 p. m. when the patient consented to an exploration.

Operation.—At 8 p. m., nine hours after the injury, operation revealed free blood and intestinal contents in the peritoneal cavity. There were three large rents in the ileum along the free border which were turned in and a very large tear in the cecum from which intestinal contents gushed out into the peritoneal cavity in large quantities. This opening was closed, drainage was inserted, but despite these efforts this patient died of general peritonitis on the fourth day postoperative.

Case VI.—J. R., male, aged forty-eight, was injured about 2 p. m. When seen half an hour later he showed evidence of shock (cold perspiration, rapid pulse, extreme pallor, etc.), and complained of severe pain in the epigastrium. The pain was localized to an area about the size of a quarter, just above the umbilicus which was marked by an abrasion of the skin. There was extreme localized tenderness about this abraded area and rigidity was limited to the same location. Here tenderness was by far a more prominent sign than rigidity. He was admitted to the Community Hospital for observation. He did not vomit but gradually reacted from his shock and the pain likewise subsided gradually. At the end of twenty-four hours most of his complaints disappeared with the exception of tenderness which persisted and ecchymosis appeared at this time over the same area. After forty-eight hours of observation, this patient was discharged.

Case VII.—J. E., male, aged thirty-two, was injured at 2:30 p. m. and when seen half an hour later exhibited a moderate degree of shock and complained of severe pain in the abdomen and the region of the umbilicus. The pain was localized to an area about the size of a silver dollar across which ran a lacerated wound about two inches long. There was a swelling (hematoma) surrounding this laceration about two inches in diameter. Palpation elicited extreme tenderness and rigidity both well localized. Pulse, temperature and respirations were normal. There was no vomiting. The patient was admitted to the Community Hospital for observation. An ice bag relieved the pain and the following morning the patient was entirely well, with the exception of extreme tenderness of the contused area. Ecchymosis appeared over the entire lower right quadrant of the abdomen and in twenty-four hours the patient was discharged.

In the first five cases the most important points, upon which the indication for an exploration were based, were the history of the injury, thoracic breathing, anxious facial expression, moderate tenderness overshadowed by the extreme rigidity (not localized), plus the absence of external signs of violence.

In Cases VI and VII extreme localized tenderness was far more prominent than the degree of rigidity and the external signs of violence were also very conspicuous. Case IX shows the difficulty of diagnosis in this class of cases. This patient was able to walk to the hospital, return, and continue at work for four hours, and travel in a crowded train for an additional hour before finally being forced to go to bed with some evidence to justify a probable diagnosis.

CONCLUSIONS.

1. All information regarding the traumatizing agent should be collected.
2. The amount of violence bears no definite ratio to the amount of injury done.
3. The more the abdominal wall is damaged, the less are the subjacent parts.
4. A diagnosis can in the majority of cases be made and to be of any value it must be made before characteristic signs appear.
5. No one sign or group of signs is absolutely pathognomonic.
6. In injuries to the abdominal wall extreme localized tenderness is the most prominent symptom and overshadows the degree of rigidity; the reverse holds equally true in injuries to the viscera.
7. Shock is not an important symptom in this class of cases.
8. The most important signs and symptoms in the order of their diagnosis value are first, rigidity followed by increased shallow breathing in the absence of distention, anxious facial expression, diffuse tenderness, deep seated, radiating pain, vomiting and shock of a varying degree.
9. The prognosis is better in injuries to the hollow

viscera, and the higher up along the intestinal track the better the prognosis.

10. Incision should be made over the point of maximum rigidity.

11. When in doubt operate, and if no visceral lesion is found, the danger to life in such an event is exceedingly small and is not to be weighed against the possible life that may be saved in many a case.

Social and Public Health Aspects of the Gonorrhea Problem*

By ALEC. N. THOMSON, M.D.,
New York.

The problem of gonorrhea control naturally divides itself into three groups: national, state, and local. Nationally, there was never much enthusiasm or backing until the great war. Then the American Social Hygiene Association which had been active prior to the war, seized its opportunity and impressed upon the Army and Navy the necessity for combating the socalled venereal diseases. With greater difficulty the interest of the United States Public Health Service was aroused. Eventually, in the national field there came into existence two governmental agencies, the Venereal Disease Division of the Public Health Service, and the Interdepartmental Social Hygiene Board, and one voluntary agency, the American Social Hygiene Association. Unfortunately, neither type of national agency evidenced much interest in the medical phase of the control of gonorrhea, unless the desire for clinics and more clinics may be so interpreted.

In 1920, the United States Public Health Service established a conference or institute, as they called it, for the study of venereal disease, and at this, medical matters did receive a fair amount of consideration, although syphilis rated more attention than did gonorrhea. The All American Conference on Venereal Disease was held the week immediately following the institute of the Public Health Service. In many respects we may consider the All American Conference in December, 1920, as having given us a statement of principles upon which we can build in combating venereal disease, and in attempting to lay down a constructive plan for more active work in the field of gonorrhea.

In the individual states it may be said that practically every department or board of health recognizes the control of venereal disease as one of the essential functions of its communicable disease campaign. Most of the states find the problem of sufficient importance to make a separate bureau or a separate division of a bureau responsible for venereal disease control work. The reason for separate divisions or departmental units is the complexity of the subject. It is not simply a medical matter. It includes education, environmental control, supervision of patients, maintenance of hospital and clinic, and close cooperative contact with the medical profession. Almost all the states have made efforts in practically every field, and have done a large volume of educational work with the printed page, motion pictures, stereopticon slides, and other means of publicity, including exhibits along the line of the anatomical museum.

The medical activities undertaken have largely been confined to the provision of better diagnostic facilities for the physician, and advice and sometimes diagnostic service for the layman. The states generally recognize the necessity for the provision of free diagnostic and treatment service for those unable to afford private service, and have contributed a good deal of money in the earlier stages of the campaign to establish clinics. Appropriations available for clinic subsidy have been cut down in most every state and in a number have been cut out. The communities, however, have been taking over the newly established clinic activities. Gonorrhea and syphilis are reportable diseases in one way or another, in every state in the union. Only nine require reporting by name. New York State has been active above the Bronx; has conducted a very extensive educational campaign for the public; has provided the medical profession with the Massachusetts General Hospital case reports in so far as they have related to either gonorrhea or syphilis; has extended its laboratory service and done an essential and creditable piece of work. But the New York State Health Department's activities do not come into our own city of greater New York.

In the cities of the country we find the same general distribution of activities, and also that the control measures have only recently assumed a position of relative importance in municipal health matters. In 1913, only twenty-eight cities out of 227 of the largest cities in the country made any effort at control of gonorrhea, and most of this effort was on the line of free laboratory diagnosis for the physician who was unfortunate enough not to own a microscope and some methylene blue. In 1921, a study of eighty-three cities was made, and there are some interesting comparisons:

In 1921, all but two of the eighty-three cities had clinics for free treatment of venereal diseases. In 1913, only four cities had them. In 1921, custodial and hospital care was available in at least thirty-eight of the eighty-three cities for the quarantine of patients refusing treatment. In 1913, hospital care was given to dangerous cases in but three cities. In 1921, examinations were given to food handlers in thirty-seven cities, and infected persons were obliged to seek treatment in order to secure working permits which were refused until the disease was rendered noninfectious. In 1913, such a law was in force in only one city. Of the eighty-three cities studied, reporting is in existence in all. Isolation and quarantine is not particularly easy, although in our own city it is decidedly a feature. Work is being carried on for the control of sex offenders, and the detection of dangerous carriers in quite a general way throughout the country. As a general thing, city health departments are offering better facilities for diagnosis of diphtheria, typhoid, scarlet fever, and tuberculosis than they are for gonorrhea and syphilis. New York City is particularly fortunate in this regard.

---

*Read before the Section of Genitourinary Surgery, March 21, 1923.

When it comes to clinics, we find that eighty-one out of the eighty-three cities studied have venereal disease clinics. It is interesting to note that the two cities without the clinics are really parts of Boston, and the patients go to the four or five clinics maintained in that city. In most of the cities, the health departments do not maintain all the clinics necessary to take care of the venereal disease work in the community, but follow the procedure which we have here in New York of clinics maintained by municipal or private hospitals. Many cities are maintaining clinics similar to the advisory clinic conducted by the New York City Health Department. A few of the cities maintain more than one clinic entirely as a health department function. Obviously, as in New York, municipal clinics may be maintained in hospitals not under the jurisdiction of the health department, as in the case with us in Bellevue and allied hospitals, and public welfare institutions. Speaking particularly of clinics maintained by health departments, it may be generally said that it is not being done to any great extent. The entrance of the health department into the field of treatment except when essential to quarantine is still being debated.

As nearly as can be ascertained, the per capita cost to the population for treating patients in venereal disease clinics ranges from one to five cents, with an average of two cents, while the cost per patient varies all the way from $2.30 to $27.00. All of which means that cost accounting in these clinics is not comparable. It may be just as good health protection for one community to spend $27.00 to clear up the occasional case in a small clinic with high overhead expense as it is for the large cities with a large clinic population and the same overhead to be giving treatment at low cost. On the other hand, there is one figure that can be reasonably measured, and that is the average per capita expenditure by community health departments for venereal disease control, which is about two cents. Some cities run as high as fourteen cents while New York City spends two tenths of a cent. The average per capita spent on gonorrhea and syphilis is one half of the average per capita spent on tuberculosis. If the propagandist is correct that there is as much syphilis as tuberculosis, and you add upon this all the gonorrhea that needs attention, then the community should be spending at least as much for the handling of the socalled venereal diseases as it now spends for tuberculosis, a disease which has apparently been declining since the discovery of the tubercle bacillus.

In New York City, a great deal has been and is being done in attacking the problem. Some ten years ago there was established in the health department as a demonstration, a diagnostic and advisory service for those afflicted with gonorrhea and syphilis. Following this, considerable effort was made to combat the quack with the passing of prohibiting legislation as far as advertising was concerned. The diseases were made reportable, and in 1917 it became "the duty of every physician to furnish and deliver to every person found by such physician, to be affected with syphilis or gonorrhea, a circular of instruction and advice, issued or approved by the Department of Health of the City of New York, and to instruct such person as to the precautions to be taken in order to prevent the communication of the disease to others."

During the past year the health department has issued new instruction leaflets on both gonorrhea and syphilis. The process by which these were written illustrates what we believe to be one of the essential factors in progress towards the better control of gonorrhea, namely a cooperative effort by the health department on the one hand, and the profession as represented by clinicians who are active in the dispensaries of the city, on the other. The health department in announcing these new publications said:

"The readers of the *Weekly Bulletin* will be interested to know that the circulars giving advice and information about gonorrhea and syphilis, which, according to law, must be issued by every physician in dispensary or private practice to persons suffering from these diseases, have been radically revised by a joint committee representing the Venereal Disease Section of the Associated Outpatient Clinics of the City of New York, and the Bureau of Preventable Diseases.

"The new circulars express not only the judgment of the officers of the Bureau of Preventable Diseases, but of a group of specialists in venereal diseases who represent all of the officially recognized venereal disease clinics of the City of New York. It is hoped that these new circulars, representing as they do the judgment of such authoritative workers in this special field of medicine, as Dr. Edward L. Keyes, Chairman of the Section on Venereal Disease, Associated Outpatient Clinics; Dr. Louis Chargin, Chief of the Division of Venereal Diseases, Department of Health; Dr. Alec N. Thomson, Executive Secretary, Section on Venereal Diseases, Associated Outpatient Clinics; Dr. D. D. Stetson, Chief, Syphilis Department, Skin and Cancer Hospital, and Dr. J. S. Read, Genitourinary Department, Long Island College Hospital, will serve a useful purpose in instructing patients and others who need to be advised about these diseases.

"The department of health has on hand a supply of these circulars, and will distribute them to patients attending its clinics, as well as to private physicians, hospitals and dispensaries. If any of the institutions desire to have an extra supply of these circulars, they may print copies of the official circular, or prepare a circular of their own which must, however, receive the approval of the department of health."

Cornell Clinic, New York Hospital, and Brooklyn Hospital have reprinted this. Every physician should provide himself with the pamphlets, to comply with the law, and do a definite piece of control work.

The sanitary code says that no public dispensary where communicable diseases are treated or diagnosed shall be conducted or maintained otherwise than in accordance with the regulations of the board of health. Under this section of the Code, regulations governing the conduct and maintenance of clinics handling gonorrhea have been laid down and printed.

Recently in an attempt to measure the practicability of these regulations, and also to ascertain how far they were being met, we circularized the institutions where we believed gonorrhea was being treated in either genitourinary, neurological, gynecological or pediatric service. We found that the clinics vary remarkably. As a matter of fact, the probability is that none of the clinics are able to comply with such hard and fast standards. In an attempt to improve the service being rendered, the Associated Outpatient Clinics of the city, through its venereal disease section is proposing to cooperate with the health department in revamping these regulations under the sanitary code. In the institutions with which you are connected there is one individual at least who is the appointed delegate of your organization to the Associated Outpatient Clinics.

Many things remain to be done. Clinics need to be improved; physicians need to consider gonorrhea as one of the more serious diseases. The jocular attitude of ten years ago is passing; is almost past. The old clap clinic is no more. Gonorrhea is being treated. Unfortunately, this is true only of gonorrhea in the male. It is doubtful whether many of the clinics in the city of New York which might come in contact with gonorrhea in the female are paying even enough attention to the subject to know that they are coming into contact with it. One of the physicians working in an institution recently stated that in the last five thousand women examined in the gynecological department, three cases of gonorrhea were found. Another leading gynecologist made the statement a couple of years ago that he thanked God that in ten years he had not seen a case in private practice. It was not so many years ago that the genitourinary surgeon, now the urologist was saying almost the same thing about gonorrhea in the male.

May the day soon come when the Gram negative diplococcus which morphologically resembles the gonococcus will no longer be a neglected inhabitant of the mucous membrane!

A Comparative Study of the Results Obtained by Counting Specimens of Blood with the Einhorn-Laporte and the Thoma-Zeiss Methods*

By HENRY A. RAFSKY, M.D.,
Attending Physician to the Lenox Hill Hospital Dispensary, N. Y.,
and
WALLACE SPIGEL, M.D.,
Norfolk, Va.

Examination of the blood has attained great significance in the clinical pathology of most diseases. The result of a blood examination, especially in internal medicine, has a great influence upon diagnosis. Frequently it is impossible to make accurate counts of the red and white blood cells at the patient's bedside, whereas it is always easy to make cover slip specimens which may be examined later.

Several years ago Einhorn and Laporte (1) devised a method of counting the red and white blood cells in stained specimens. As this method was practical, accurate, and at the same time simple, the idea occurred to us to compare the results obtained by this method and the Thoma-Zeiss method (3).

We obtained the specimens of blood for the two counts at the same time. Then one of us counted the blood by the Einhorn-Laporte method and the other by the Thoma-Zeiss method. We counted the blood in forty-nine cases and proceeded as follows:

In each case the blood under the necessary precautions was first drawn into the red and white pipettes of the Thoma-Zeiss apparatus. Then cover glass preparations were made according to Ehrlich (2). One of us (S.) determined the number of red and white cells according to the Thoma-Zeiss method. The other (R.) counted the blood by the Einhorn-Laporte method.

In making the cover glass specimens no pressure should be exerted to force the blood from the puncture, but it must flow out freely just as it should for use in the mixing pipettes of the Thoma-Zeiss apparatus. All the precautions essential to a good spread as given by Ehrlich should be scrupulously observed in the distribution of the blood between the cover glasses, namely a very thin carefully cleansed cover glass, not too large a drop, and other technical details. In the same manner the blood must be spread out evenly between the cover glasses by means of capillarity without the exertion of any pressure.

---

*From the Lenox Hill Hospital, New York.

If all these necessary precautions are taken specimens suitable for subsequent examinations are obtained. The specimens are stained by Jenners stain.

Starting from the supposition that in carefully prepared specimens, the distribution of the blood elements will vary correspondingly according to their number, we decided to count all the red as well as all the white corpuscles in a certain area of the dry specimen and to compare the results thus obtained with those by the Thoma-Zeiss method. As the unit of the square area counted we have taken a square millimeter. The number of red and white corpuscles contained in a square millimeter is calculated from the fields counted multiplied by a certain constant factor and the result is then compared with the number of red blood cells contained in one cubic millimeter as described by the Thoma-Zeiss apparatus.

TECHNIC.

For making this determination we have found a medium power dry objective (D D or E of Zeiss or 5, 6 or 7 of Leitz) with a weaker and a stronger eyepiece most practical. We used objective D D and eyepiece 2 and 4 of Zeiss. With objective D D and eyepiece 2 the whole visual field comprised 0.23 square millimeters. The field area can be easily determined for each objective and eyepiece according to the well known algebraic formula, which makes the square area of a circle equal to R^2 where $\pi = 3, 1,415$ and R=radius of circle. The radius of the visual field is determined by means of a fine stage micrometer or the divisions in the Thoma-Zeiss counting chamber.

Objective D D and eyepiece 2 we used only to count the leucocytes in the whole field. As it would be impossible to count also the more numerous red cells in so large a field, we contented ourselves by counting a certain fraction of the whole field. For this purpose we used the same objective D D but with eyepiece 4, into which for further reducing the field we inserted a glass diaphragm engraved in the centre with a large square, which again is subdivided into four equal squares. This diaphragm is similar to the one used by Einhorn and Laporte but is a circular piece of glass made so as to fit into the ocular of the microscope. The rulings on this glass are the same as used by these authors in their work.

COUNTING.

After preparing the cover glass specimen and selecting a suitable area, we count with objective D. D. and eyepiece 2 all the leucocytes visible in the field. After changing eyepiece 2 for 4 into which we have placed our blood counting diaphragm, all the erythrocytes visible in the entire square aperture or some part of it are counted. Now reinsert eyepiece 2 and move the slide for the width of one field. This procedure is repeated until about six square millimeters (twenty-five fields) have been counted. From these figures the number of leucocytes and erythrocytes in one square millimeter of the cover glass specimen is calculated. The number of leucocytes in one square millimeter is found by simply dividing their total number counted by the number of square millimeters counted. With the reds we proceed in a similar manner except that we have to multiply the resulting quotient by the number which indicates how many times the entire field of eyepiece 2 is larger than that of the field embraced by the square aperture of the blood counting diaphragm in eyepiece 4. In our case this number was 20.3.

All we have to do now in order to obtain the number of corpuscles in a cubic millimeter is to multiply the numbers counted in one square millimeter by the average factors (500 for the red and 400 for the white cells).

Below we have appended a table of forty-nine cases. These cases represent the counts by the Einhorn-Laporte and the Thoma-Zeiss methods respectively.

In making a blood count the personal equation plays an important part in the result. A marked difference will occur when two persons draw blood from a patient and make two separate counts by the same method. Again, a blood count made by the Thoma-Zeiss method will rarely give the same result even if the blood should be drawn at the same time and counted by two persons as Table II shows. Therefore, there is sure to be a difference between the result obtained by counting the blood by the two methods. But the variation is not on the whole any more than would be if separate counts were made by two persons at the same or different times and counted by the same method.

In going over Table I, it will be seen that the difference in the white blood cells between these two methods is as follows:

In twenty-six cases there was a difference of less than 1000.
In eighteen cases there was a difference of 1000-2000.
In five cases there was a difference of 2000 or more.

The red blood cells vary as follows:

In thirty-eight cases there was a difference of 50,000 to 250,000.
In eleven cases there was a difference of over 250,000.

CONCLUSIONS.

In comparing the Einhorn-Laporte method of counting specimens of blood with that of the Thoma-Zeiss, we find the former has these advantages over the latter:

In the Einhorn-Laporte method the blood specimen can be taken at the bedside and counted at leisure. It is a rapid, accurate and very convenient method. It can easily be done by every physician without the need of a special blood counting apparatus. The differential count can be made from the same specimen at the same time.

Report of Glandular Dysfunctions in One Family

By JANE BALDWIN, M.D.,

Assistant to Neuro-Endocrine Clinic, Neurological Institute, New York City,

New York.

The following family history is reported not because it is unusual to find many glandular dysfunctions in the same family, but because it is rather unusual to find such endocrine embalance in practically an immediate family.

The father, an American of English descent, married two sisters, also American and English descent. By the first wife he had two daughters and two sons. The daughters married, one twice, and both remained sterile. One son showed criminal tendencies, absconding with a large sum of money. His marriage was also sterile. The second son, a typical cretin, lived to the age of thirty with most marked cretinoid symptoms as to features, skin, stature and intelligence. By the second wife he had three daughters. The wife herself died of diabetes. The oldest daughter only attained a height of five feet, suffered with scant, irregular menses and had such marked hirsuties that she was forced to shave daily. The two younger daughters became very obese, married and both proved sterile. I regret being unable to trace the family tree back to previous generations.

This family then shows marked uniglandular as well as pluriglandular dysfunction. The pancreas in the diabetic mother, the thyroid in the cretin son, the pituitary, gonads, pineal, and the suprarenal cortex one or more, in the remaining members of the family.

Editorial Articles

THE VALUE OF VACCINATION

If any form of treatment or prevention has been proven beyond a doubt it is vaccination against smallpox. The evidence in support of vaccination from all parts of the world is so overwhelming as to admit of no argument, and yet in some civilized countries and especially in Great Britain where the method was discovered and introduced there is a considerable amount of scepticism as to its beneficial effects in both preventing smallpox and modifying its virulence, and indifference among a large proportion of the population as to its value. The educated persons who prate glibly of the misconceived views which have arisen concerning the efficacy of vaccination and attribute the subsidence of the disease and the apparent alteration of type to improved sanitation, hygiene and so on and who declare that vaccination has been a negligible quantity in this practical abolition of the dread malady are, speaking frankly, mischievous. They lead the ignorant, and the mass of the population are supremely ignorant of medical matters, astray to the menace of the entire community. When vaccination has not been in force for a long period, there are a large number of persons who are not protected against it, and if infection is abroad are apt to contract a virulent form and moreover to spread it. Vaccination, therefore, should be made compulsory for the sake of the public at large and the ignorant led away by specious argument must not be allowed to be an ever present source of danger to a nation.

Liberty, freedom, and individualism are excellent when used with discretion, but when these watchwords are employed to be abused and everyone is permitted to use his own judgment, or lack of judgment, at the expense of his neighbors, it is time to call a halt. Recently Sir Patrick Hehir, a retired major general in the medical service of the British Army in India, has contributed some most instructive data on the value of vaccination in India and in the Near East which supply a striking object lesson upon he theme of this editorial. In a communication he made a short time ago to the lay press of London he said in part that as health officer of a large municipality in a native state in India for a period of ten years (1887-97) he came into contact with much smallpox, and had a great deal to do with vaccination. n 1888, in an official report he represented that about wenty per cent. of the community were disfigured, or had lost one or both eyes, or were deaf, from the effects of smallpox. Epidemics that ran into thouands of cases used to occur. By 1897 the disease was almost eradicated from that municipality solely by compulsory vaccination, systematically carried out. It may also be added that smallpox is practically always present in an epidemic form in the civil population in one or more districts in India, yet it never occurs epidemically among Indian troops, chiefly because every native soldier must be vaccinated as a condition of his recruitment.

During the first half of the present year Sir Patrick Hehir, when working for the British Red Cross Society in Greece, saw somewhere in the neighborhood of eight hundred cases of smallpox in refugee infectious diseases hospitals and in the Red Cross Hospitals. To all intents and purposes these cases occurred in adults who had not been vaccinated and children who had never been vaccinated. It was not until nearly the whole of the refugee population had been compulsorily vaccinated that the disease was got in check.

It is also pointed out that the old arguments that used to be advanced against vaccination when it was carried out on the socalled arm to arm system, can no longer be maintained. Vaccine lymph is now in almost all instances obtained from healthy calves. Personally Sir Patrick Hehir has been vaccinated five times, twice successfully. It has fallen to his lot to have been brought into contact with many thousands of smallpox cases. He has never had the disease.

The testimony in support of vaccination must convince any but the most prejudiced or ignorant of its efficacy. Of course, improved sanitation and hygiene generally have been favoring contributory causes in the doing away with smallpox, but it is certain that vaccination is the main factor in a successful campaign against its spread. In India, for instance, sanitation is at a very low ebb, although, no doubt, slightly improved, and this goes to show that in the district in which Sir Patrick Hehir was health officer vaccination was the method which virtually eradicated the disease. Again among the refugees in Greece, sanitary and hygienic conditions were low and smallpox flourished abundantly until compulsory vaccination checked it. But there is no need to dwell further on the point and especially to medical readers, that vaccination properly done is the only sure means of wiping out smallpox. However this may be said, is it right that the population at large of a country should be made to suffer or likely to suffer because of the views of a few cranks and because of the ignorance of medical matters, comprehendible of course, of the many? An educational campaign on several diseases might and undoubtedly would prevent a great deal of sickness both acute and chronic. In fact, vaccination and smallpox show up this fact most strongly and point the moral that vaccination should be made compulsory and universal and that education on medical matters should be carried on by those who know more widely than at present.

HOSPITAL CARE OF PATIENTS

Little or no thought has been given to the problem of the hospital care of patients suffering from chronic diseases, in spite of the fact that the last thirty years have witnessed a great improvement in the standards and policies of the general hospitals. The series of articles dealing with the institutional care of sufferers from chronic disease, that has recently appeared (The Proper Institutional Care for Patients with Chronic Diseases, Ernst P. Boas, *The Modern Hospital,* November, 1922, and Present Institutional Facilities for Care of Chronic Diseases, Ernst P. Boas, *The Modern Hospital,* November, 1922, and July, 1923), is, therefore, quite timely.

Of fundamental importance is the classification of the inmates of such institutions according to the care which they demand. The author points out that they may be grouped into three categories: Class A—those requiring medical study for diagnosis and treatment; Class B—those requiring nursing care only; Class C—those requiring custodial care only. The classification is important because it brings to mind the different institutional facilities demanded by each group. Class A patients are entitled to all the resources of a general hospital; Class B patients should command an excellent nursing service, controlled by a conscientious medical staff; Class C patients require only custodial care and are retained in the hospital for economic, not for medical reasons. They remain because poverty prevents their relatives from receiving and caring for them.

The institution caring for patients with chronic diseases, therefore, must be prepared to give three types of service and must consciously plan its organization accordingly, if the patients are to be properly cared for and if the institution is to be economically conducted. The final paragraph sums up the author's conclusions: "Such hospitals must be equipped with all of the facilities of a general hospital. They should retain in their wards only such patients who need active medical and nursing care. In connection with such hospitals there should be a separate pavilion for purely custodial cases. A method of free transfer between the two departments of the institution should be established. A home for incurables should have no independent existence without immediate access to complete hospital facilities."

MALARIA AS A REMEDY

While malaria is allowed to be the most destructive and devastating disease known, it is now said to possess certain therapeutic virtues. It is a matter of common knowledge gained by experience that patients suffering from progressive paralysis, a late stage of syphilis, when seized with an acute affection accompanied by high temperature, improve. This fact suggested to Professor Wagner-Jauregg, of Vienna, that it might be beneficial to inoculate such patients with the germs of malaria. This was done, and after some eight to ten attacks of fever had been undergone, the malaria was stopped with quinine. In a lecture recently delivered in Vienna, it was stated that cases thus treated in good time which had not been favorably influenced, in the least, by salvarsan, resulted in an improvement lasting for years and even in rehabilitation for work. It seems, however, that the importance of this treatment rests chiefly on the question as to which centre of the brain is affected by the stimuli of syphilis. If an essential part of the brain is injured, although the paralysis may be stayed, of course, there is no cure.

The claim is made, that since 1919, three hundred cases have been treated in this manner at the Wagner-Jauregg clinic. It is further declared that owing to the new method the number of paralytics who have to be nursed at asylums has declined. It appears that the main aim of this mode of treatment is to eradicate syphilis during its early stage by artificial malaria so as to prevent paralysis which may break out later.

Professor Wagner-Jauregg method is being practised at the Steinhof which is the second largest lunatic asylum in the world.

More must be learned of this revolutionary method of treating syphilis and a great deal more experience must be gained and accurately recorded ere it can be regarded and employed as an effective means for preventing or favorably influencing progressive paralysis.

POSTOPERATIVE PNEUMONIA

Postoperative pneumonia cases are all too common and many of them could be prevented with a little more forethought and care. When we consider one little custom of hospital practice it would seem nigh miraculous that pneumonia, whether postoperative or as a complication in a medical case, is not more common. That custom is the placing of a patient, who has just come from a warm bed to which he is accustomed, in several warm blankets—in one blanket of routine hospital accommodation or possibly two. The hospital supply may be theoretically ample, but from nationality, family, custom, and individual nature patients cannot all be treated alike. Chilling of the body is still, as it has always been, the antecedent of colds and of pneumonia, and when a bath, none too carefully administered, and a few hours in bed with insufficient or unaccustomed clothing, is followed by the shock of an operation, the wonder is that pneumonia does not develop more frequently.

Carelessness in the washing of a patient after operation so that his wrappings are soaked and he is not completely dried before going to the recovery room is a source of chill. The recovery room treatment may lead to pneumonia and a successful surgeon has recently called our attention to the danger from too prolonged treatment for shock by external heat, and there is probably very much truth in his assertion. Possibly the operating room is often warmer than is good for the patient, with all his wrappings. Does anyone know how warm an operating room should be? We doubt whether the matter has ever been studied. But many postoperative pneumonias are really preoperative pneumonias which a careful examination would have disclosed. A surgeon of our acquaintance recently operated upon a hernia in a case in which the operation might have been delayed indefinitely except that delay added to compensation outlay. An examination of the chest revealed some râles, but the man was vigorous and the surgeon took the risk. The patient died within a few days of pneumonia.

Postoperative pneumonias are frequently attributed to the action of the anesthetic, but if this were the true cause such outcome ought to be much more frequent than they are. It may be that the anesthetic is often a factor, but it probably is of slight importance compared with other conditions, some of which we have mentioned.

EXCESS WEIGHT

Time was, and not long ago, when weight above normal in the adult was believed (except in extreme cases) to be a protection rather than a harmful condition, while underweight, at any age, was considered significant of increased tendency to premature mortality. Just the opposite is the view now held by the ,insurance companies with regard to heavy weight in adults, and they tell us that those who have reached the age of thirty and who are below the average weight for their height have a decided advantage in the race for length of days.

Were the statisticians wrong in their assertions of a few years back, or were they simply following the common notion that because one is well padded he must be in excellent health? It is barely possible that the near disappearance of typhoid fever as a frequent cause of death and a source of life long injury to ten times as many persons as it killed, may have brought about the change of view and actual change in the showing of statistics. At any rate it was held, and doubtless with good ground, that a person furnished with a superabundant stock of internal provision for a siege of sickness in the form of typhoid infection was much better prepared to weather it than your individual of normal or of subnormal weight.

It stands to reason that unless excess fat is an aid in infections (and certainly in our present day most common and most fatal infection—pneumonia, it is not an aid) it ceases to be of any apparent benefit. On the other hand the mere carrying around, day after day, of fifty, twenty or even five extra pounds of weight means so much more wear and tear on the locomotor machinery and, in particular, upon the heart. We would consider it absurd to carry all day a five pound weight in our pocket, or one pound in each of our five pockets, but five pounds of fat, though more widely distributed, is just as heavy. Is it any wonder that socalled heart failure is of frequent occurence, especially if that heart is already weakened by infection. Excess weight means also excess feeding, excess work on the part of the kidneys, and, sooner or later, poisoning of tissues by a lymph that cannot always be kept normal. There is every physiological reason why the present teachings of the actuary in regard to heavy weight in persons in adult life, should be true.

THE PATHOLOGY OF PHLYCTANULAR CONJUNCTIVITIS AND KERATITIS

Ivanoff, in 1869, was the first to describe the pathological histology of phlyctanular keratitis and conjunctivitis, but the process has been given much study so that at present the histology is fairly well known. The epithelium, according to Leber, is simply raised up and decreased in thickness from the periphery to the centre of the nodule. It becomes strongly infiltrated with leucocytes and then its limits with the mucosa upon which it rests become more and more ragged, infiltrated as it is by these elements. At the centre of the nodule the epithelium is changed and to all appearances in a state of passage to necrosis. The protoplasm is very stained, while on the contrary, the nuclei are less so and are irregular; the cells are flattened and placed in irregular order. Therefore, when destruction of the epithelium takes place the borders gradually drop and become confounded in an imperceptible slant with the loss of substance. The latter is occasionally covered by shreds of epithelium on the point of withering but at no spot is there anything which gives the impression of a retracted vesicle. On the contrary, the process has its seat in the mucosa which is swollen from a copious leucocytic infiltration. By a closer examination of the intimate structure of the nodule, it is found not to be merely an infiltration of polynuclear leucocytes, but that larger cells of another aspect participate in the formation of the nodule. While the peripheral zone is infiltrated by small polynuclear leucocytes in great quantity, the cells at the centre of the infiltration become gradually larger and closer together, their protoplasm is more strongly stained and their nuclei larger. They vary in number from one to several. Giant cells with peripheral nuclei, occasionally numerous and large, are also found. Leber attributes considerable importance to the giant cells around which he believes the nodule develops.

No foreign body or tubercle bacilli have been detected in these giant cells, neither has caseification been found in the rest of the tissues composing the lesion. The vessels present thickened endothelium with cells projecting into their lumen, which sometimes obstruct it completely and the discovery of giant cells in the vessel walls has led to the opinion that they are the result of an increase in size of the endothelial cells.

According to von Michel the phlyctena at one phase of its development forms a cavity filled with liquid and he describes three phases. In the first the epithelial cells in the affected area of the conjunctiva offer a normal aspect and among them are to be found numerous polynuclear leucocytes mixed with bits of nuclei. The epithelial cells are massed together at certain points while their structure is changed because they are compressed by superficial hemorrhage. He also noted a deepseated hemorrhage which formed a thick layer of blood. The component tissues were infiltrated with polynuclear leucocytes and the vessels dilated. In the second phase the upper layer of epithelium is traversed by leucocytes at many places, while between the superficial and deep epithelial layers the aspect of a vesicle can be made out. At this spot numerous epithelial cells are changed, sometimes degenerated, their nuclei staining less.

Polynuclear leucocytes are found in the centre as well as a mass of fine fasciculi, forming a broad layer at the lower epithelial stratum. The conjunctival tissue is greatly infiltrated with polynuclear leucocytes. All this is characteristic of vesicle formation.

In the third phase—that of definitive repair—there is an elimination of necrosed epithelial cells and at the bottom of the loss of substance fission cells are seen massed together. On the neoformed young connective tissue the epithelium regenerates and this is why at this point that the epithelium is separated from the connective tissue of the nodule by vesicles which are the débris of former hemorrhage. The lesion offers the aspect of a young cicatrix.

All observers excepting von Michel admit a nodular structure of the phlyctena and the majority reject the possibility of a vesicular phase. According to Wagenmann no necrosed tissue or fibrinous infiltration are to be found either in the cornea or conjunctiva. Sattler maintains that after rupture the phlyctena remains solid and is crater shaped. Wintersteiner never found the subconjunctival hemorrhage met with by von Michel, while Axenfeld, Wagenmann and Rosenhauck reject the tuberculous structure of the phlyctena in which no tubercle bacillus has ever been found.

The term phlyctena is a misnomer because the lesion is essentially composed of a subepithelial nodular mass of polynuclear leucocytes. By its structure and giant cells it approaches a tubercle but it differs from the latter in as much as tubercle bacilli have not been found, likewise caseification.

SMALLPOX

The smallpox menace is likely to be an increasing one in this country as it is in others where there has been a decrease in the percentage of those vaccinated against the disease. In some recent epidemics in this country the death rate showed an increasing malignity, and was a warning that the diagnosis of the disease and its prevention are becoming of the greatest importance.

It is interesting to see that in a country where health work has had a longer and larger share of public support than in this country there are districts as benighted and obtuse in such matters as our own. The experience of the city of Gloucester, England, is one which we may expect, however, to have repeated on this side of the water. This city of some fifty thousand people had recently 150 cases of disease which the city fathers and others interested in the city's trade rather than in her health interests, were intent on believing to be chicken pox. The local health officer, likewise, seems to have followed this lead. However, the Health Officer from Birmingham was called in, pronounced the disease smallpox and sent them to a hospital.

The city fathers became irate at such proceedings and were also incensed that the local newspapers should give publicity to the facts in the case. Gloucester was getting into bad repute and the only way out of it seemed to be to suppress the truth. At a meeting of the city council the qualifications of the Birmingham Health Official were questioned, whereupon that gentleman promptly left the meeting, telling them that they would have to get someone else to steer them through their plague and that he was leaving town. This action brought the council to its senses, and one of its members exclaimed, "Dr. Davidson has come here to save the city and we have treated him like a dog." A resolution of thanks and of confidence was then passed and presented to Dr. Davidson by a committee headed by the Mayor. The outcome of the Gloucester epidemic will probably be wholesale vaccination, for ninety per cent. of the population is said to be unvaccinated.

In this country we have had recently the picture of a department of education in a large city opposing the department of health in its efforts to check an epidemic of smallpox by vaccination, and this does not argue for a very rosy future for the subduing of such outbreaks. Possibly only severer epidemics can make us duly appreciative of the benefits of vaccination.

MILK ANAPHYLAXIS IN GASTRIC CASES

For a long time milk has been extolled as a food and especially for the purpose of providing a nutritious substance, freer than most other foods from irritating properties, in the treatment of gastric cases. Only a few years ago a doctor who threw doubt on the suitability of milk as the main if not the sole diet of persons suffering from gastric disorders would have been regarded with suspicion as to his mental state. Dr. F. J. Smith, late consulting physician to the London Hospital, was one of the first, if not the first, to change the routine practice of giving nothing but milk to those recovering from typhoid fever. He ordered meat and a mixed diet and obtained better results from this revolutionary treatment than physicians who continued to restrict the diet of their typhoid patients to milk.

Dr. Harry Campbell, also of London, has preached against the universal use of milk as a food in and out of season for years. He takes the stand that man is by heredity a carnivorous animal or, perhaps, rather a mixed feeder, that he is intended to eat hard food requiring mastication, and he argues that after childhood has passed milk is an unnatural food. Dr. Campbell states as his opinion that the early decay of teeth, the prevalence of digestive disorders and, indeed, many of the ills to which man is prone and suffers from are due to the consumption of soft pappy foods and too much sugar. Of course these views are not general, but, at the same time, they are gaining ground and, moreover, the time honored custom of feeding patients suffering from gastric diseases chiefly on milk is falling somewhat into disrepute.

At a meeting of the Medical Section of the Royal Academy of Medicine in Ireland, held in Dublin on January 5th last, the president, Dr. I. Gilman Moorhead, read a paper on milk anaphylaxis in which he protested against the almost universal and indiscriminate use of milk in cases of gastric disorder. While not denying the nutritive value of milk, and its soothing properties in many cases, such as gastric and duodenal ulcer, he voiced his conviction that, speaking generally, milk was not made for man, and that many gastric troubles were prolonged, and even made worse by the restriction of diet to milk and milk foods. It does seem a sound argument which Dr. Moorhead advances, or rather agrees with, that if an individual loathes milk, as certain persons do loathe it, it cannot be scientific practice to order it.

Sir John Moore agreed with Dr. Moorhead that milk sometimes was one of the worst things which could be given to patients. In cases of enteric fever he had often seen milk acting as a poison, and in such cases he had substituted whey and egg water. Dr. L. Abrahamson said that he had known a case of mucous colitis no better after being treated on a milk diet for about two years. The patient when put on meat juice made a complete recovery.

Dr. I. J. D. Lane said that the point in these cases was to find out if, when milk disagreed, it was due to anaphylaxis or not. If a patient gave an anaphylactic response to ordinary milk and not to boiled milk, he thought that was a point in favor of anaphylaxis. Several others took part in the discussion and all registered their opinion that milk was more or less frequently a harmful or an unsuitable food in gastric cases.

Is it the truth, then, that the value of milk both in health and in sickness had been exaggerated? To some extent, this statement may be true. Undoubtedly due consideration should be given to Dr. Harry Campbell's assertion that milk is not a food for adults, and that the conformation of our jaws and teeth show that we were intended to subsist on meat and food requiring mastication chiefly, with a sufficiency of vegetables and of food containing the vitamine elements in proper quantities. In fact, a diet of adequate metabolic equilibrium, in conformity with climate and manner of life.

With regard to milk in gastric cases it appears that with some frequency this fluid is not indicated, at least not as a sole diet, even when no distinct milk anaphylaxis exists. Lastly, it must always be borne in mind that, so far as milk as an article of diet is concerned, it is essential that it be free from contamination and that infection be wholly absent. Milk may be a dangerous food and the utmost care must be taken to render it safe. The question of its value in gastric cases is most interesting and the opinion of medical men on the subject would be of value.

THE ALMSHOUSE

It is a fact not generally recognized that over sixty per cent. of the inmates of almshouses are sick or infirm. The death rate in almshouses is very high and almost twenty per cent. of deaths are due to tuberculosis. The high death rate is not chargeable to the advanced age of the inmates, for over forty per cent. of those who die are under the age of sixty and twenty per cent. are under forty. Most of these patients suffer from chronic disease. It is selfevident that the provisions for the care of chronic patients must be inadequate in the innumerable small county almshouses scattered throughout the country. Not without reason has it been said that "the county almshouse is a hospital with the hospital part left out."

On the face of it, it is impossible to expect small county almshouses, with limited budgets, to furnish adequate facilities for the care of their inmates. The only opportunity for improvement will come from a development analogous to the movement which removed the insane from the almshouses and assembled them in large state hospitals. Such state hospitals will have to be planned for the specialized purpose of giving proper medical, nursing and custodial care to their inmates. A careful study of this problem is urgently indicated. (Present Institutional Facilities for Care of Chronic Diseases, Ernest P. Boas, *The Modern Hospital,* July, 1923.)

◆

News Items.

First Harvey Lecture.—Dr. A. Biedl, Professor of experimental pathology at the University of Prag, delivered the first Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, October 13, 1923. His subject was Organotherapy.

To Open Gallstone Clinic.—A free clinic for gallstone sufferers will be held daily from 10 a. m. to noon at the Good Samaritan Dispensary, Essex and Broome Streets, by Dr. Ulvi Goldenberg, Vienna specialist, who recently arrived in this country. Dr. E. W. Lipschutz, of Brooklyn, will assist Dr. Goldenberg.

Insulin Given by Rockefeller.—Provost Josiah H. Penniman, of the University of Pennsylvania, announces that John D. Rockefeller, Jr., has given to the university $10,000 to be used in treating with insulin a large number of ward and dispensary patients suffering from diabetes, and to teach physicians in general practice the proper method of employing insulin in the treatment of diabetes.

Physicians and Red Cross.—The medical profession in New York City is cooperating with the Red Cross in its annual Roll Call, which opens Armistice Day, November 11th and continues until Thanksgiving, for the enlistment of new members to maintain the organization's peace time program of relief and public health work. Dr. Frederick Tilney, of New York, is chairman of a special physicians' and surgeons' committee, formed in accordance with the campaign plan of organizing the entire city into various groups to facilitate the Roll Call effort.

Dr. Lorenz Returns.—Dr. Adolph Lorenz, Viennese bloodless surgeon, accompanied by his son, Dr. Albert Lorenz, are back in America. Dr. Lorenz will go to Buffalo, N. Y., at the invitation of the Mayor, and there conduct a clinic. Later he will return to New York and be associated with Dr. Yeager at 471 Park Avenue.

Memorial for Dr. Pryor.—On October 10, 1923, the Buffalo Academy of Medicine will hold a memorial service in honor of John H. Pryor, M. D., F. A. C. P., one of the founders of the academy. The services will be held at 8:45 p. m. before the section meeting in the Fillmore Room of the Hotel Statler. This memorial service is held in cooperation with the Medical Society of the County of Erie and the Physicians' Protective Association.

The Centenary of the *Lancet*.—A dinner is to be given in celebration of the hundredth anniversary of the *Lancet* which will be held in London on November 28, 1923. Sir Donald MacAlister, president of the General Medical Council of Great Britain, will be in the chair, and he will be supported by the president of the Royal Society, the president of the Royal College of Physicians of London, the president of the Royal College of Surgeons of England, the Minister of Health, chief medical officer, president of the Royal Society of Medicine, and the president of the Medical Society of London.

Four Free Clinics to Be Open.—Four free clinics where medical, neurological, psychiatric and psychological examinations and treatment according to the best modern scientific principles will be given by specialists, will be opened by the Jewish Board of Guardians, supported by the Federation for the Support of Jewish Philanthropic Societies. The clinics will be available to all men and women under the board's supervision. The psychiatric clinic will be under the direction of Dr. Dudley Schoenfeld of Mount Sinai Hospital; psychopathic and glandular treatment will be given by Dr. Spencer Strauss of the Postgraduate Hospital; Dr. N. Thomas Sax, pediatrician of the Postgraduate, will be in charge of the medical clinic, and Dr. Max Schultz, of the same hospital, will head the neurological clinic.

Interchange of Health Officers in the United States.—An event of deep interest for world health is the third general interchange of health officers arranged by the health section of the League of Nations which is now taking place in the United States. Representatives from France, England, Italy, Russia, Poland, Spain, Holland, Belgium, Greece, Jugoslavia, Germany, Switzerland, Norway, Mexico, San Salvador, Brazil, Chile, and Canada, delegated by their respective governments to participate in a course of study and observation, arrived in America the first week in September and will remain for approximately three months. Until September 22d the delegates will remain in Washington, studying national health organization as administered by the United States Public Health Service. Following the close of the course of study of the national health agency the delegation will separate into three groups in order to study state and local health departments.

Foreign Correspondence.

SOUTH AMERICAN LETTER

(*From our own correspondent.*)

BUENOS AYRES, ARGENTINE, *August 1, 1923.*

CRUISE OF AMERICAN COLLEGE OF SURGEONS.

The recent cruise of the American College of Surgeons, organized for the purpose of increasing our knowledge of South America and stimulating friendly relations with the people, and more particularly the surgical profession of these republics, was a great success. It was an opportunity never before offered to such a large body of medical men. They were everywhere received with the most open handed hospitality; receptions being arranged for them where we met the presidents of the republics visited. The American ambassadors did everything in their power to make our visit pleasant. To get the proper perspective we must bear in mind the struggles through which these republics have gone and how very recently stable governments have been established in many of them.

CUBA.

Cuba, the last to have thrown off the Spanish yoke, shows the influence of the brief American occupation and its close proximity to the United States in the manner in which their hospitals conform to American standards, particularly in good screening, ventilation, and training schools for nurses.

PANAMA.

In Panama, while most of the time was spent in the canal zone, which is strictly under American control, we could still readily see that the Panamanians were not slow in adopting the lessons in sanitation which were responsible for converting this pest hole into a veritable tropical health resort. While there the surgeons had the pleasure of being present at the laying of the cornerstone for the Gorgas memorial institute of research in tropical disease and preventive medicine.

If, as the result of the work of this institution and others such as the Oswaldo Cruz Institute in Rio Janeiro, our knowledge of tropical disease increases as much in the next twenty-five years as it has in the past, and our preventive measures keep pace, it will mean that this vast area will be opened to occupation by the white people of these countries and their wonderful natural resources be furnished to the markets of the world. The schools and hospitals are supported and controlled by the state. Some of the hospitals have hospital boards.

MEDICAL SCHOOLS VISITED.

The medical schools were found to be most complete in the way of buildings, laboratories, etc. A seven year course is required for graduation, and one wonders why the men turned out are not superior to ours. On closer study we find there are over fifty holidays exclusive of Sundays each year so that the actual hours required is not greater than with us and added to this a tropical climate which is not conducive to full speed probably tells the story at least in part. The private patients are taken care of in sanatoriums owned by the various doctors. Some of these were as fully equipped as anywhere in the world, and most excellent work being done.

Their public hospitals were, as a rule, large, clean, and well ventilated, but lacked screening and proper nursing staffs. The operating rooms were large, not screened, and poorly ventilated, which defects are being slowly overcome. The nursing problem is a hard one, the better class girls being taught to look upon nursing as menial, and until by education this attitude is changed the outlook is poor.

The surgery seen in the public hospitals while in the main good was not all of the first order; in certain cases the vital principles being sacrificed to speed.

ARGENTINE.

The disease which excited the most interest, perhaps on account of its frequency, especially in Argentine and its rarity with us, was echinococcus disease of the various organs of the body. It was not at all unusual to see from one to five of these cases being operated on in a single clinic in one day.

The procedure was usually under a general anesthetic to expose the cyst, and after due precautions being taken to prevent contamination of the surrounding tissue, to aspirate through a large trochar as much of the contents as possible, then to clean out the remaining daughter cysts and drain, if complete dissection was impossible. Many of them remained cured but I saw patients being operated on for the third time. Most of the surgeons showed the effects of foreign training, particularly French, and many of the instruments used were of French manufacture.

GENEVA LETTER

(*From our own correspondent*)

GENEVA, SEPTEMBER *20, 1923.*

CONGRESS OF MEDICINE AT HELSINGFORS.

At the recent congress of medicine held at Helsingfors, E. H. Jagerskiöld discussed a topic of considerable interest, namely, the capillaries in pernicious anemia and other affections of the blood based on the results obtained by capillaroscopy. Examinations of the capillary loops at the root of the nails with a power of fifty diameters, in cases of pernicious anemia, were found very pale, indistinct, filiform and irregularly distributed under the skin. The venous segment was abnormal and larger than the artery while the short connecting segment—often assuming a figure eight in shape—was of small calibre. Usually the blood current was rapid and homogeneous in the smallest capillaries and interrupted in the larger ones. Normal peristaltic contractions were not observed and compression of the vessels of the arm failed to produce them. But when the compression was released, just enough to allow the arterial flux to pass, a segment of the capillary vessels became gorged with dark colored blood and other loops which had not been in evidence appeared in the field presenting the same conditions.

In cases of pronounced anemia—with about 1,000,000 red cells—the capillaries were indistinct, very pale with a greatly accelerated blood current. In cases of medium intensity the capillary loops were better filled and higher in color.

In mild anemias, the aspect of the loops did not vary much from the normal but it is interesting to note that a clinical amelioration of the patients was often accompanied by a change of aspect of the capillaries and although such changes were not constant, this resulted from other factors present.

In simple anemias similar pictures are seen but in chlorosis nothing of the kind takes place, the loops only being somewhat pale. In Vaquez's disease, the capillaries abound, gorged with reddish brown blood and occasionally three to seven times larger than normal. Peristaltic movements were active and the blood current irregular.

All things considered, it may be assumed that the state of capillary plenitude depends upon the amount of the mass of blood and this is why it is mild in anemias and high in chlorosis and polyglobulia. At any rate this procedure of exploration should be of great interest for following parallelly the blood count during the clinical evolution of high grade anemias.

ANDRÉ THOMAS, OF PARIS, ON VASCULAR SPASM.

Since we are discussing the vascular system, I would like to refer to the recent work done by Dr. André Thomas, of Paris, on the question of vascular spasm in intermittent claudication as opinions greatly differ in respect to this phenomenon. From very exact and complete experiments carried out in two cases in order to elucidate the provocative cause of the spasm, this observer has been able to show that, generally speaking, many local and distant factors may be quite sufficient in these patients on account of the arteritis present as well as a special sensibility and spasmophilia. Light massage, passive movements of the toes or metatarsus, pressure exercised over the inalleolae may provoke paleness of the skin and then cramplike pain which prevents walking. Pressure over the iliac crest or horripilation over an extensive area of the body may also be followed by a vascular constrictive crisis.

It would therefore seem that when the act of walking causes the spasm, a number of causal factors come into play and not a single one, so that the mechanism of the spasm is a complex one. But a most interesting point to which I would call attention is that with the oscillometer one can detect the early commencement of these same vascular changes in perfectly healthy subjects when submitted to provocative tests and active or passive movements of the lower limbs. Therefore, it is probable that the disturbances of intermittent claudication are merely exaggerations of a rupture of the equilibrium between the arterial and venous systems ordinarily occurring during the act of walking.

PIERRE GIRAND ON STERILIZATION.

A very good thesis (Paris, 1923) has just been issued from the service of Prof. Couvelaire, by Dr. Pierre Girand on the sterilization of hereditary syphilitic infants. Girand takes pains to show the necessity of searching for syphilis in the parents at the onset of every pregnancy, especially if the gestation is abnormal. If parental syphilis has been detected, the mother should, of course, be treated during pregnancy and the infant should be treated after birth for not less than eighteen months. The Wassermann reaction is frequently negative although clinical manifestations of syphilis are present. Continue treatment after a positive Wassermann has become negative. Then, after a prolonged rest from treatment reactivate, in order to test the blood serum and cerebrospinal fluid.

On account of ineffective treatment of poisoning by mushrooms, Dr. Dujarrie de la Riviére has recently undertaken to prepare a serum which, it would seem, has been successful, if one may judge from his report to the Academy of Medicine of Paris. By using a toxin extracted from a mushroom of the gender *aminata,* this observer immunized horses by progressively increasing doses—a procedure necessitating very great precautions—after which he studied the action of the serum in rabbits and mice.

The serum has an unquestionable prophylactic value, a fact made evident by first subcutaneously injecting the serum, after which the toxin is injected into the peritoneum. By simultaneously injecting the serum into the marginal vein of one ear in a rabbit and the toxin into the other ear, the animal remains well. When the serum is injected subcutaneously or intraperitoneally during the first two hours following an injection of the poison, the serum neutralizes four lethal doses of the toxin. A mixture of serum and toxin allowed to stand for one hour and then injected into the peritoneal cavity of an animal was found to remain neutral.

LONDON LETTER.

London, *July 25, 1923.*

DINNER OF THE BRITISH FEDERATION OF MEDICAL AND ALLIED SERVICES AND THE NEW CANCER MOVEMENT.

The Federation of Medical and Allied Services, although a comparatively recent institution, if it may be termed an institution, has taken root and is flourishing apace. This is convincing evidence that it supplied a want and is working along the right lines. It is usually the custom in this country to celebrate an anniversary or anything of that sort by a dinner and, of course, the federation upholds this good old English habit. Its annual dinner was held at the Langham Hotel, London, on May 29th last, Sir Berkeley Moynihan, the president of the federation, being in the chair, and the Minister of Health, the Rt. Hon. Neville Chamberlain, the principal guest.

The chairman, in proposing the health of the Minister, said, in part, that the community was at last beginning to take an interest in public health and that was all to the advantage of the federation. If cancer was only to be cured by early research it was essential that the public should be educated to discover and report themselves very early in regard to those departures from health which cancer declared. It may be here interpolated that the federation has had a great deal to do with the organization of the new campaign against cancer which has been inaugurated in Great Britain and which is being conducted as vigorously as circumstances permit. In fact, the federation is attempting earnestly to make an alliance between medicine and the public. Trying to educate the community to the advantages of preventive medicine, nursing, pharmacy, industrial hygiene, and so on, and in the principles of preventive medicine in the broadest sense of that word, the federation is acting or endeavoring to act as a "go between" with regard to medicine and the public, in so far as instructing them in the precepts and practice of modern medicine are concerned.

Sir Berkeley Moynihan pointed out that public health could no longer be studied unless the public played their part. One of the lessons learned during the war was that no campaign could be planned or launched unless regard was paid to the casualty lists, for the strength and striking power of the army depended upon the health of the troops. It was the same in industry as in war, and captains of industry were beginning to realize that if they were to carry on their work with the largest profit they must regard the welfare of the men working under them. In this connection the federation is playing an important part. Its annual report showed that industry after industry was beginning to realize that the federation was giving them substantial help in this matter, but if the work was to extend and grow it was necessary that further financial support should be forthcoming. The great resources of the federation in technical knowledge were at the disposal of the Ministry of Health and the federation would be proud to be made the medium of help in every possible way.

The Minister of Health, in responding, said among other things that he was glad to hear Sir Berkeley Moynihan refer to the cooperation with industry, because he felt convinced that that was a valuable sphere of operation. Regarding the many diseases that prevailed, the causes of which were obscure, it seemed to him that there was nothing they could more fruitfully devote their attention to than the furthering of research. But more opportunities and more inducements must be provided for men to engage in research. Doctors could not do that and at the same time carry on a general practice in order to live. It could not be doubted that the efforts made in recent years to grapple with scarlet fever, measles, cancer, and other dangerous enemies of mankind had borne good fruit, for in the years that followed the war, despite all its consequences in suffering and depression, the vital statistics of the country were never so favorable. He supposed that some day they would have a complete health policy for the country, and it would have to come about under a minister who was fortunate enough to remain in office for more than a few months at a time. He did not pretend to say what that policy would be, but he thought we could even now see where our weak spots lay. The institutional accommodation was inadequate. We have physicians and surgeons second to none, and we do not make the best use of their services, nor of the nurses. To attain an efficient health policy all the resources at our disposal had to be used, and it was because the federation could help in that matter that he wished it all prosperity and success.

As pointed out, the province or the self-appointed task of the federation appears to be to educate the public with regard to medical matters in order that lay members of the community may be induced to take an intelligent concern in health affairs. Matters concerning which people are ignorant are generally regarded with indifference or with distrust and there are many phases of preventive medicine of which the masses are grossly ignorant. It is one of the main objects, then, of the federation to inform them on obscure points and to try to make clear to them that medical research, for example, is for the benefit of the people at large, although few of the results may be immediately evident if at all. Cancer is a subject regarding which the public is profoundly ignorant, nor, it may be said, are medical men themselves well informed. But the public is commencing to recognize the fact that malignant disease is taking an increasingly heavy toll of the population and if they become convinced that if certain measures were introduced the disease could be prevented to some extent, they would adopt such measures. Medical men do know, and know little more, that the only chance of diminishing the mortality and suffering from cancer is early diagnosis and early effective treatment. Doctors also know that while, up to the present time, research and investigation have yielded no definite results, in some directions, the outcome has been encouraging and that it is well worth while to continue efforts of every kind to unveil the mystery of cancer.

In Great Britain an organized campaign against cancer is about to be carried on zealously. An important communication has been published in the lay press throughout the country over the signature of these well known men, Sir Napier Burnett, head of the Hospital Service of the British Red Cross Society; Lord Dawson of Penn, an eminent London physician; Lieutenant Colonel F. E. Freemantle, an army medical officer and a medical officer of health; Dr. John B. Farmer, professor of botany and director of the biological laboratories at the Imperial College of Science and Technology; Sir R. C. Garton, director of Lloyds Bank; Colonel Sir C. Gordon Watson, surgeon at St. Bartholomew's Hospital; Dr. R. A. Gibbons, Sir Thomas Horder, Lieutenant Colonel Knox, of the Indian Medical Service; Mr. G. Locker-Lampson, M.P.; Mr. J. Lockhart Mummery, senior surgeon at St. Mark's Hospital for Cancer; Sir E. Marshall-Hall, K.C., a celebrated advocate; Mr. J. Beaumont Pease, deputy chairman of Lloyds Bank; Sir Bernard Spilsbury, late honorary pathologist at the British Home Office; the Hon. Sir Arthur Stanley, chairman of the Joint Council for the British Red Cross and the Order of St. John, Sir William Willcox, scientific analyst and medical advisor to the British Home Office.

VIENNA LETTER

(*From our own correspondent*)

July 5, 1923.

MEDICOSOCIAL LECTURES.

The syndicate of forensic reporters of the Vienna journals has requested Dr. Julius Tandler, the world wide known anatomist of the Vienna University, the social democratic sanitary advisor of the City of

Vienna, to hold a scientific lecture on some medicosocial topic. Professor Tandler complied with the request with pleasure, and held his lecture on February 19th in the spacious hall of the Vienna Concert House, which was crowded by an audience consisting of hundreds of physicians and the most distinguished lay public of the capital. Professor Tandler is extremely popular in Vienna, all hygienic reforms of the republican Vienna are connected with his name. For instance, the erection of the so much discussed crematorium, the marriage advising bureau (*Ehebcratungsstelle*) and the advisory bureau for sexual patients (*Bcratungsstelle für Geschlechtskranken*) are all his creations. He wrote a memorandum during the war, on the hygienic conditions of Austria. Emperor Charles consulted him on sanitation matters in the field, and the newspapers remarked, when reporting this interview, that Professor Tandler was audacious enough to give his socialistic opinion about the conditions caused by the war also to the late Emperor. During the war he was invited several times by the Social Science Association in Budapest to hold such lectures. After the revolution he became State Secretary for Public Hygiene, but he could not remain long in this position because he longed after his university chair and after one and a half years keen work as State Secretary he abdicated from this position and returned to the university to teach anatomy again.

CHILD HEALTH.

The health of children, he said, was never the point of view of populating policy. It was always money that played the chief rôle, and never the welfare of the new generation. Even wives had a subordinate rôle in the interest of defending property, she herself being in principle the property of the husband. With all ancient cultured nations the wife has been the slave of her husband, and the law of wife has been obedience. Nowhere do we see between husmand and wife the relation of uniformity of rights. The revolution of 1789 approached the emancipation of women, in a certain measure, but this was still very far from that which could satisfy the requirements. After the revolution a capitalist world philosophy followed, and in this world order we find women divided into three classes, industrially: 1. The life of the richest women, who have absolutely no necessity to work, even the education of their children and their housekeeping are done by paid women. 2. Women of the middle class, who, in most cases, have to work within their own homes. 3. The working women, who have to work for wages. The marriages of the last type of women are generally said to be unhappy, the unhappiness being due only to economical conditions.

The basis of the populating policy is the valuation of men. The higher the degree of the culture of community, the greater value is given to men. The war has thrown European culture back to the times when human life was very cheap and all became accustomed to the thought of violent death. The populating policy regards as its organic capital the family. This capital can be increased both as to quality and to quantity. The quantitative augmentation is an ancient principle. The Jehovah of the *Old Testament* promised as a reward that they would increase in number as the sand of the sea. We should not forget the quantitative augmentation was an imperialistic policy. It does not mean anything else than the strengthening of the armies, and the fortifying of those in power. The great number of births mean more soldiers. And the other directing principle of this policy is a mercantilist one: to create sufficient hands for the machines. The greatest sin of this policy is that it does not wait until the maturity of adults, but it blemishes the picture of society with puerile working power.

BIRTH RATE.

The true socialistic populating policy acknowledges in the first line the right of every man towards the values of life. By this reason the increasing of the birth is not more important for this policy than the decreasing of mortality. We see that in France births are encouraged by premiums given by the State, but no premium is given for decreasing mortality. The French people are accused by its own Government of being sexually perverse, arguing that this is the cause of the low birth rate. But this is a false statement. Sexual perversity is not responsible for the low birth rate, but poverty, and economical misery. If we compare the mortality rate of the civilian and working classes, we see that in the former on an average eighty-two per cent. are reaching the sixteenth year of life, while in the working class scarcely fifty. Births are not to be encouraged, but the preservation of lives by conditions of living worthy of men. Another wise institution would be the compulsory maternity enacted in a law. At present the obligation to become a mother does not refer to the rich people. These, by reason of their female culture, get the necessary enlightenment, which enables them to evade the possibility of fecundation. The women of the poorer classes, however, have to take recourse to the most dangerous procedures for want of enlightenment and money. The time is ripe that in case of artificial abortions dealt with before the courts not only the developing childlife, but also the interest of the woman should be represented by the State experts.

Poverty decimates people, but the modern medical sciences are likely to govern mortality with great success. The illegitimate children are those who mostly succumb in the difficult economic conditions. The modern social politics does not know girl mother and illegitimate child. Only mother and child. The foundling houses are the remainders of out of date institutions. We are endeavoring in Vienna that a mother shall be able to educate her child born out of wedlock at least as well as a legitimate child. We condemn the erroneous policy of our State, said Professor Tandler, spending eighty milliards for old age pension and forty-four milliards for the treatment of the insane; in consequence of these vast figures the State Treasury is unable to spend more than 67.5 milliards for children protection, although if the larger sum would be spent for the protection of children later on we had not to keep so many incapacitated men.

It is our chief duty toward the children that the parents shall be healthy. We have to awaken in men a feeling of responsibility toward the coming children which will save the new generation.

Book Reviews

THE HEART

Ieart Records. Their Interpretation and Preparation. By S. Calvin Smith, M.S., M.D., Philadelphia. F. A. Davis Co., 1923.

This volume is intended by the author as an elenentary guide for those who would familiarize themelves with electrocardiographic and polygraphic nethods. The book is eminently practical and avoids ll speculations and hypotheses. After a brief disussion of the physiologic basis of electrocardiogaphy, Dr. Smith discusses the normal electrocarliagram and the interpretation of abnormal records. ll controversial points have been avoided. The ollowing chapters deal in considerable detail with he technic of electrocardiographic methods. The eginner will find many valuable practical hints vhich, if carefully observed, will help him avoid umerous pitfalls and annoyances. The final chaper is devoted to a brief discussion of polygraphic nethods and tracings. There are 126 original illusrations, well chosen and reproduced. It is refreshng to find in a book devoted to electrocardiography he statement that "Heart records can only supplenent—they can never supplant the painstaking linical examinations." In this volume Dr. Smith as achieved his purpose of giving a simple but adeuate and accurate presentation of the elements of lectrocardiography and polygraphy which will be f real service to the medical student and to the beinner who would familiarize himself with these raphic methods and their interpretation.

SKIN AND VENEREAL DISEASES

ehrbuch der Haut-und Geschlechtsleiden (Einschliesslich der Kosmetik). By Sanitätsrat Dr. S. Jessner, Königsberg. Sixth and Seventh Revised and Improved Editions. Leipzig: Verlag von Curt Kabitzsch, 1923.

The first volume, Skin and Cosmetics, and Formuıry, covers the subject of dermatology and cosetics, in a clear, easily understood fashion, that akes a strong appeal to the student or the practioner who desires a working knowledge of skin iseases. This is not a volume for the specialist ut for the general practitioner and student. In ypography and arrangement it is all that could be esired. The colored plates are true to life and finely ortrayed. Special chapters deal with dermatoscopy, ermatotherapeutic remedies and the internal treatent of skin lesions. The latter includes the subects of internal chemotherapy, vaccine and serum erapy and organotherapy.

The second volume deals solely with the three enereal diseases, gonorrhea, syphilis, and chancroid. hese subjects are treated in the usual way, parcular emphasis being laid on pathology and treatent. Salvarsan and its derivatives occupy the vored position in the treatment of syphilis, though fairly large number of arsenical and mercurial reparations of German origin are favorably menoned as altenatives. The relation of marriage to philis is seriously considered at length, from a beral point of view, conforming in general with the ost recent opinions on this question.

Permanganate irrigations and the silver salts are favored in gonorrhea, but there is a noticeable omission of endoscopic and operative measures in the therapy of chronic gonococcal infections characteristic of medical opinion in the United States.

On the whole it may be said these volumes represent the prevailing confidential methods of diagnosis and treatment, and constitute a safe guide for the practitioner and student, though the second volume could be improved by the inclusion of some of the recent work on the seminal vesicles done by American venereologists and urologists.

SURGICAL DIAGNOSIS

Chirurgische Diagnostik (in Tabellenform für Studierende und Arzte). By Dr. Med. A. J. Cemach, Vienna. Third and Fourth Improved Editions. Munich: J. F. Lehmanns Verlag, 1923.

This edition is an improvement upon the second (1921) edition by changes in the text and tables, and by the addition of a number of new röntgenographs and plates, bringing the work up to date in every detail.

The author has produced a volume of extreme utility and beauty. There are very few pages of text matter and the tables are conveniently arranged, showing at a glance the differential diagnosis and the actual diagnosis of the subjects described. The result of this unusual arrangement is a volume of comparatively small size, covering practically every conceivable surgical condition that might be of interest to the student and the surgeon. The illustrations in black and white and the colored plates are placed in juxtaposition to the tables as closely as practicable, thus visualizing the subject in the most practical manner. The plates and illustrations are true to nature and exceedingly beautiful from the artistic point of view—an important feature in any book dealing with surgery.

This attractive work surely must retain the popularity which has characterized its predecessors, for which there was a demand for three editions within the short space of two years. It is a volume that any one interested in surgery can study at the same time with profit and pleasure.

MEDICINE

A Synopsis of Medicine. By Henry Letheby Tidy, M.A., M.D., B.Ch. (Oxon.) F.R.C.P. (Lond.). Third Edition, Revised and Enlarged. New York: William Wood & Co., 1923.

In the arrangement of this rather pretentious work the author has followed that of Osler's "Principles and Practice of Medicine" with few exceptions. This volume is not intended to be a textbook, but a synopsis, having for its object to assist those who find it necessary to cover the ground in a short space of time. We believe the author has succeeded in producing a volume that cannot fail to be of great assistance to the medical student or the busy general practitioner involved in a doubtful diagnosis or therapeutic problem, with little time or inclination to wade through cumbersome textbooks.

The present revised edition contains much new matter, new articles having been added on veronal and cocaine poisoning, Vincent's angina, cyclical vomiting, coeliac disease and sprue; also on the tests of renal efficiency. Yellow fever has been removed from the section on Diseases of Unknown Etiology and transferred to that on the Spirochetal Diseases, due to the researches of Noguchi.

The volume is carefully written, compact and truly a valuable synopsis of present medical knowledge; but, as the author well says, it can never take the place of the textbook. As a matter of fact, he does not desire that it should.

UROLOGY

The Urethra and the Urethroscope—A Manual of Practical Urethroscopy. By F. Carminow Doble, M.R.C.S., L.R.C.P. (Lond.), with Foreword by Major A. T. Frost, O.B.E., R.A.M.C. London: Henry Frowde and Hodder & Stoughton, 1923

Recognizing the fact that works on venereal diseases, even the largest, allot but little space to the subject of urethroscopy, the author very commendably has produced an attractive and useful volume dealing with the urethra and its examination in health and disease by means of the urethroscope. Unfortunately for American readers, the instruments employed and described in the book are entirely European, the American instruments not receiving sufficient recognition even to be mentioned by name. Notwithstanding this shortcoming from the American point of view, the work is one of decided merit, though rather elementary in some respects.

There is an excellent chapter on urethroscopy and its technic in the female. The printing and paper are of unusually fine quality.

PSYCHOANALYSIS

Some Applications of Psychoanalysis. By Dr. Oskar Pfister, Pastor in Zurich, Switzerland. Authorized English Version. New York: Dood, Mead and Company; London: George Allen and Unwin, Ltd., 1923. Pp. 352.

Pfister's enthusiastic loyalty to psychoanalysis and that as it is given by Freud makes of this book an ardent plea for psychoanalysis both as theory and as practice. His own breadth of culture with his special training in the psychological field and in philosophy give his writing a rich background. It makes him competent to compare as he does in one very interesting chapter the systems or part systems which various men have deduced from Freud's original theory. He presents as in all his writings stimulating reports from his own successful work with psychoanalysis. Yet his thought is governed rather overwhelmingly by the idealism toward which he would have psychoanalysis tend in its results. His wish, exalted and stimulating as it is, too greatly dominates his thought. His own philosophy of psychoanalysis is not put forward with that fundamental clearness which he himself extols in Freud's stricter empiricism. He is not finally convincing in all that he says—is some of it perhaps the fault of the translation of expression none too clear in the original tongue? Or is it due to Pfister's religious idealism which crowds him in an over anxiety to reinterpret all the findings of psychoanalysis to the service of his own great ideal? Perhaps, for example, psychoanalysis can render, as he believes, definite service upon the mission field. It surely should aid to valuable psychological revelations. But Pfister's high claims for Christianity as over against other religions strengthen one in the feeling that his empirical acumen of vision is somewhat clouded by the enthusiasm of his own projected vision.

PSYCHOLOGY

Medical Psychology and Psychical Research. By T. W. Mitchell, M.D. New York: E. P. Dutton and Company, 1923. Pp. vii, 244.

Mitchell submits to examination certain phenomena observed in medical psychology which he considers part of the legitimate material for psychical research. These are the phenomena of hysteria, manifestations of multiple personality and in hypnotism the striking appreciation of time evidenced chiefly in those totally amnesic to the hypnotic trance, technically in "somnambules." Careful observation which takes account of all facts but with strict regard to their authenticity marks the presentation of the author's material, both his own and that gathered from other observers. His is one of those larger minds which can afford to wait before interpretations are made or conclusions drawn. There is deep appreciation of the affective possibilities behind the dissociations of consciousness which appear, a recognition of the subject's own participation in bringing about his condition, be it hypnosis, obedience to suggestion or the splitting of the personality which is glaringly manifest. The writer is inclined therefore to interpretation without the introduction of any supranormal factor but even here he refrains from prematurely conclusive dogma. He has not entered into the revelation of the individual affective content which might underlie the material set forth but he has not left this affective material without reference to its existence and significance. He especially acknowledges the guidance of Janet and Freud, the former as giving the most aid from the merely descriptive standpoint, the latter as performing much more fruitful service from the standpoint of interpretation. Mitchell's own thought is profound as he follows inquiringly the phenomena which he reports.

MAYO PAPERS

Papers from the Mayo Foundation and the Medical Schoo of the University of Minnesota, Volume II, 1921-1922 Philadelphia and London: W. B. Saunders Company, 1923

Nearly all of these papers, more than a hundred in number, by ninety-two authors, were presented originally as theses by graduate medical students of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science or Doctor of Philosophy. There are also a few papers other than these graduate student theses, and a few on various phases of medical education by members of the graduate faculty.

The first volume of similar papers which appeared last year was so favorably received that the publication committee felt justified in offering this second volume. A glance at the table of contents will convince the reader that the subjects enumerated cove an unusually wide and interesting field, and the perusal of the articles themselves, clearly written and freely illustrated, will more than justify this conviction.

There is an extremely interesting paper on The Laws of Heredity and Their Application to Variou

Conditions in Man, by J. Arthur Buchanan, in which migraine, essential epilepsy, inheritance of the blood group, diabetes mellitus, essential asthma and protein sensitivity are studied from the standpoint of heredity. The author reaches the almost revolutionary conclusion that "the data presented are criteria against the continuation of the use of the expression 'inheritance of susceptibility to disease.'" He concludes that no evidence has been presented in the study of heredity to show that characters are susceptible of appearing or that there is a tendency for them to appear. They are either present or absent. There is no uncertainty.

PHYSICAL THERAPY

Therapeutics of Activity. By ANDREW A. GOUR, M.G., D.O. Chicago: Covici-McGee, 1923.

In the introduction to this volume, the writer claims "this book rightly understood will settle the question of specific activities for everyone." The author evidently has attempted to include in a book of some 400 pages the entire scope of exercises from the ordinary home gymnastics to sports, games and medical gymnastics. In the beginning the author attempts a defense of the Ling system as if the value of the Ling system, properly carried out, were not appreciated. Throughout the book the value of medical gymnastics is brought out, the author repeatedly adding that for the full effect, necessary osteopathic adjustments should also be performed. Everything from rhinitis, tonsillitis, pleurisy, tuberculosis of the lungs to prolapsus of the rectum is given more or less the same outline of treatment. Flat foot, according to the author, is cured through adjustment of the innominate or superficial lesions below the eleventh dorsal vertebræ, but the exercises mentioned cure only fifty per cent. of the cases without spinal adjustment. In inflamed hernias, which according to the author are due to injury of an irreducible hernia, he advises every possible means to empty the bowels, including castor oil and salts. Surgery is mentioned to prevent strangulations.

Throughout the book innumerable faulty physical principles and pathological processes are emphasized. The book is poorly written, filled with cheap photographs, and aside from the statement of the already accepted Ling basic principles, contains little that would be elucidative to the medical man and less that could be made of value to the layman.

THREE STORIES BY LAWRENCE

The Captain's Doll. Three Novelettes by D. H. LAWRENCE. New York: Thomas Seltzer, 1923.

Lawrence has come into his own again with the publication of this last volume of short stories. Together with *Sons and Lovers* we feel this marks the height of his achievement. The other volumes show him always alert, making the most of the curious finds he draws from the dunghill of common lives. Perhaps our taste is too puritan. But in our opinion being true to life has its best and most tasteful expression in only these two of Lawrence's fiction works.

When he expatiates on psychoanalysis we are sorry for him. He is almost ludicrous. But when his characters live themselves with all their psychopathological vagaries we welcome his pages as a remarkable guide to the technic of the very subject he does not seem to be able to express as such. In these three novelettes he gets back to his own and fundamental themes—the mother fixation—which he resolves in three different ways.

We have the drawing together of opposites, complements, in the sphere dubbed abnormal, but now found to be so nearly universal that we are forced to shift to "bisexual" as a better designation. There is in everyone the possibility of developing one or the other side of his nature according to the fate he meets. The Captain, reborn in a child-craving lover's skill as a doll, is seeking the eternal mother. The older woman he has married, her premature aging in body and mind, and her final complete identification with his mother that costs her her life, are but stages in the sex history of many patients. The Captain then has to replace this mother. He seeks the creator of himself (the doll) and finds the Countess Hannele on the verge of marrying a father substitute. She has battled for her personality until she is tired. She now wants to be protected but not "bothered." So the Captain with his offer of a life of hero worship and motherly prostration for her fulfills both their needs.

The Fox takes up the mating of two homosexuals. March, the woman, has played the male role in her farm household with the frail, neurotic woman friend. The red fox, the dreamed-of fox brush across her face, are calls from the unconscious of her dormant womanhood. Then when the youth who is mentally identified with the fox comes upon the scene there is uproar. He not only kills the fox and kills the friend, but effectually lays the ghost of March's nascent femininity. All her fixation objects converge in him. They marry, and then wonder why she is depressed! They count upon the new beginning in the new country to shake her out of herself. Perhaps it will. Any call upon her self-reliance would probably be effective. For she is psychically of the aggressive type and her mating with another aggressive bodes constant conflict for both of them.

The last story, *The Ladybird,* is the most curiously wrought. It is a beautiful texture of human unconscious motives, as changing and as subtly interwoven as a piece of music. The story is difficult to describe. The Bohemian count, undersized, exotic, son of outlaws, appeals to the Junoesque, conventionally bred daughter of an English wildling. Her mother is perfection, so the father is made to conform, the daughter is married to the suitable man. The war flings everything into a common mill, and brings Count Psanek, wounded and a prisoner to England and reckons the husband among the missing. The wounded man recovers; the husband is found. In the course of a triangular houseparty after the war, Lady Daphne becomes the day-time wife of her husband who confesses to much deeper regard for her as a sister being than as a sex mate, and the night wife of the Ladybird, last of that romantic clan. In itself rather a crude consummation of three adults' difficulties. But in this case Lawrence is not crude and by the magic of his touch leaves us feeling that it really is only to be expected.

◆

Medicoliterary Notes.

An interesting and valuable document, the reading of which would be well worth while to all physicians interested in medical education, is a memorandum entitled *Recent Advances in Medical Education in England,* published by the Ministry of Health. Sir George Newman is the compiler and writer of the document. It outlines advances made in the teaching of the preparatory sciences, in anatomy, physiology, pharmacology and therapeutics, pathology and bacteriology, the clinical study of medicine and surgery, the chief needs of clinical study, university clinics, obstetrics and gynecology, preventive medicine in medical practice; the special subjects associated with medicine, namely, pediatrics, psychology and psychopathology, ophthalmology, venereal disease, dental education, and public health. The appendices contain the revised medical curriculum of the General Medical Council, the revised regulations of the Conjoint Examination Board, and other information connected with the subject.

* * *

The Illinois *Health News* reports that a typhoid carrier who, it is stated, had an attack of this disease fifty-three years ago has been found by one of the field physicians of the State Department of Public Health. He is the owner of two cows, the milk from which was indicated as the avenue of transmission of a small epidemic of typhoid fever. This case is the oldest, in point of typhoid carrier state, that has ever come to the attention of the Illinois health officials.

* * *

Among the States reporting an increase in the number of summer cases of typhoid fever are Indiana and New York. The New York State Department of Health has urged all physicians, especially those of this city, to cooperate in all possible ways in educating people in methods of prevention.

* * *

An interesting case of rabies is commented on in a recent number of the *Journal of the American Medical Association.* A young girl in California was attacked by a mountain lion and severely bitten. She made an uneventful recovery, but seven weeks later developed hydrophobia and died from it. A boy who had been badly scratched by the lion at the same time also died. The case is of interest as it is the second on record of a mountain lion's attack on a human being without provocation; also, hydrophobia in a mountain lion is a curiosity. No other instance is on record. According to the California State Board of Health, rabies has occurred in that State in horses, mules, cattle, sheep, goats, hogs, domestic cats, dogs, wildcats, coyotes, and once each in a ground squirrel and a gray fox.

* * *

The United States Public Health Service is issuing a valuable series of pamphlets giving venereal disease information for use in its cooperative work with the State health departments. A recent issue is of special interest since it contains special articles on general paresis by Dr. Paul E. Bowers, and on the trend of venereal disease incidence; there are additional sections on the subjects of research, diagnosis, treatment, and clinical, public health, and administrative notes.

* * *

Faint Perfume, by Zona Gale, is a disappointment after her former novels, especially *Miss Lulu Bett,* which was dramatized and had a successful run in this city two winters ago. *Faint Perfume* is slight in plot, rather hectic in style, and does not seem to ring quite true as a picture of life. The character drawing of Grandfather Crumb is the one masterly stroke.

* * *

The National Health Council reports that New York State led in the amount of health legislation adopted during the sessions of recent months of the lawmakers of fourteen States. Aside from purely local measures, the majority of the laws have to do with food, drugs, tuberculosis, child welfare and municipal health.

* * *

The Manhattan Health Society, of 502 West 163d Street, furnishes to its members, for a small fee, supervision for pregnant mothers, assistance at confinements, visiting nurse care for the sick, baby health service, health supervision for children, and instruction in simple nursing care.

* * *

The Institute of Industrial Research in Washington recently made tests of the sterilizing power of paint, which showed that a painted area has a negligible bacterial growth, which may be removed by washing, and that infected surfaces may be made sterile by painting.

* * *

A report on infant mortality and its causes in Baltimore has just been published by the United States Children's Bureau. According to this report it is found that the chief conditions causing high death rates among babies under one year were poverty, employment of mothers outside the home, housing below the proper standard, short intervals between births, and the deaths of mothers at or soon after childbirth.

* * *

Lehigh University Extension School will offer during the coming year a course in the handling of backward children in public schools. The study methods will be based on observation of the occupation therapy classes in the State Hospital.

* * *

Dr. Frankwood E. Williams, medical director of the National Committee for Mental Hygiene, will give a course of lectures at the New School for Social Research on mental hygiene and its social bearings. Methods of investigation, general types of disturbed mentality, and the broad conclusions of modern psychopathology will be studied in turn.

Practical Therapeutics

THE ADVANTAGE OF INTRAORAL OPERATION IN EXTENSIVE DISEASE OF THE JAWS

By Bertram B. Machat, D. D. S.,

Brooklyn.

Success of any enterprise is frequently determined by the manner or method of its attack. This is true in surgery and particularly so in operations upon the jaws.

In extensive osteomyelitis or fracture of the maxillæ, or both, the intraoral and extraoral methods of operation are practiced; it depends largely upon the peculiar experience of the operating surgeon. Thus, in the hands of the mouth surgeon the intraoral route is the method of choice. This has proved highly successful as may be seen from the vast number of minor and major operations involving laceration which are daily performed under conditions of incomplete—oft impossible asepsis; yet postoperative complications are comparatively rare.

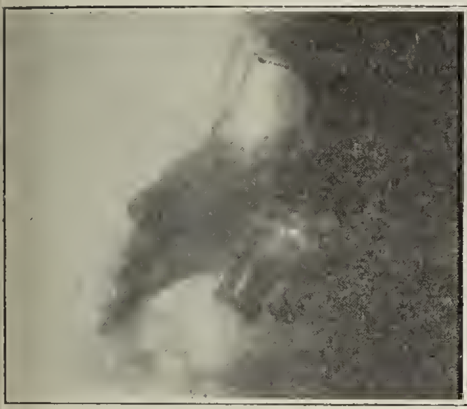

Fig. 1.

Fig. 2.

Fig. 1. Shows the right mandible before operation; decalcification and fragmentation is readily seen.

Fig. 2. Shows the condition of the left mandible following the first operation, the large dense mass in the anterior portion is due o the iodoform gauze packing, note also the large sequestrum in the region of the chin.

Contrasted with this the extraoral route is more readily accessible and permits of absolute asepsis, however, despite these added advantages—healing akes longer while postoperative sepsis is not uncommon. So, too, the extraoral approach in the removal of sequestræ or resection entails more radical surgery.

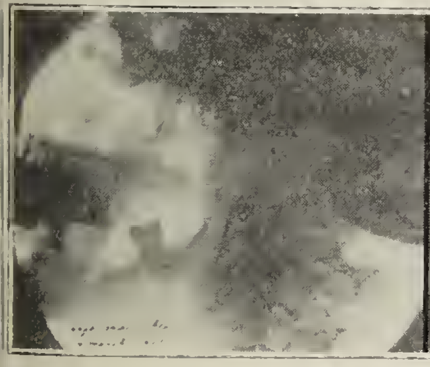

Fig. 3.

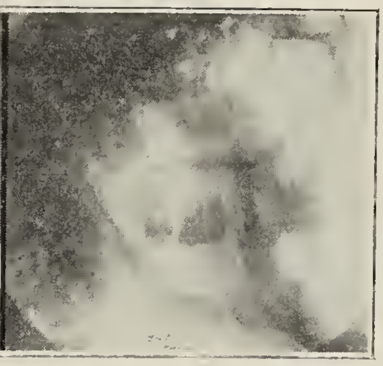

Fig. 4.

Figs. 3, 4. Show the condition of the mandible (right and left) eight months after operation. It will be seen that osteogenesis is well advanced.

Unlike other bone operations, the mere removal of extensive pathological conditions from the mandible is not sufficient for success. Indeed, rehabilitation of dental articulation and contour symmetry is extremely important, for without mandibular function and correct cosmetic result, a deft surgical operation may yield a poor prognosis.

That extensive maxillary surgery can be accomplished intraorally, in that way obviating esthetic disappointment and with less sacrifice of savable tissue may be gathered from the following case report.

It should be added that in the hands of the modern oral surgeon, block anesthesia is employed thus insuring greater safety as well as cooperation by the patient—which is a most important factor in mouth operations—while the long anesthesia affords a painless and clean procedure.

The case here reported is one of osteomyelitis of the mandible.

Case.—Male, aged fifty-one, driver, married, six children, apparently robust, presenting a nonpainful but considerable swelling of the right mandibular and submandibular region with a large copiously discharging sinus facially in the region of the first molar—was admitted in the Greenpoint Hospital, May 8, 1921.

Intraorally several discharging fistulæ extending from the right retromolar region to the left mental foramen were noted. The mouth was foul, purulent, ill kept and with the exception of four teeth in the posterior region of the left mandible—the latter was edentulous. In the maxilla, most of the teeth were in situ, but peridentally they were deeply involved, several carious teeth and root fragments obtained here.

Excepting a furunculosis several weeks prior to admission at which time, too, most of the teeth in the lower jaw were removed, the personal and family history were negative, so was the Wassermann; while Neisserian infection was denied. The blood count showed 17,000 leucocytes, eighty per cent. polymorphonuclear, seventeen small and three large lymphocytes.

On palpation a crepitous fragmentation presented while caseous like purulent substance was expressed. A diagnosis of osteomyelitis of the mandible was made.

The operation was performed intraorally under bilateral block anesthesia in two sittings: novolprocaine being the anesthetic employed. Upward of twenty sequestræ were removed, leaving, however, a substantial part of the lingual wall and lower border fairly intact. Healing took place without complication, there being no rise in temperature nor hemorrhage. The patient was discharged from the hospital May 21, 1921, and from clinic, June 15, 1921.

SOME OPHTHALMIC CONTRAINDICATIONS TO THYROID THERAPY

By Philip A. Harry, M. A., M. D.,

Rochdale, England,

Honorary Ophthalmic Surgeon, The General Infirmary, Rochdale, England.

Thyroideum siccum now occupies a foremost place among the substances prescribed by physicians and in recent years ophthalmic surgeons have come to rely more on its aid. It has proved valuable in many corneal conditions, especially where an effect on metabolism is indicated. Several authors have reported cases of uveitis benefitted by the administration of thyroid extract. James Bordley (1) described clearly the reasons for prescribing it empirically. He noticed the changes which occurred in the thyroid gland following severe infections and the part it played in the fight against these conditions, and the success gained with the use of thyroid encouraged him to record his cases.

The treatment of all forms of uveitis still leaves much to be desired and ophthalmologists have always welcomed new views on the subject. Percy Dunn (2), of London, demands a wider application for this form of treatment. He holds that the thyroid exercises a protective, antitoxic, and immunizing action, defending the body, not only against toxic products of its own metabolism, but against invasion by disease producing microorganisms and injury by their products. He thus shows hypothyroidism to be of manifest import in ophthalmic practice.

Two conditions are frequently associated with this state, namely intestinal putrefaction and septic foci such as pyorrhea alveolaris; these excite reactionary processes to which the eye shows a disproportionate responsiveness. He calls attention to the value of thyroid in the various anomalous eye symptoms complained of by patients at the menopause. Further, among the signs of thyroid inadequacy is hemorrhage. The common form of subconjunctival hemorrhage, usually attributed to gout and its analogue subretinal hemorrhage, both point to hypothyroidism in his opinion.

It has been shown that many of the conditions associated with and giving rise to arteriosclerosis could be benefitted or controlled by the administration of thyroid. It will be admitted, therefore, that the more or less empirical use of this substance has given rise in many cases to satisfactory results and has even tended to arouse enthusiasm beyond justifiable limits and although the absence of a miraculous result is no proof of its failure it may, however, serve a useful purpose to call attention to some of the limitations of thyroid therapy.

During this year in two cases that have been under treatment there developed conditions that were directly due to the administration of thyroid.

Case I.—Annie W. came up complaining of deficient vision in the left eye. There was a low degree of myopia in the right eye (—2). With the correcting lens the right vision was 6/6. Left vision 6/60, not improved by glasses. The refraction was similar in each eye. Examination of the left fundus showed a shallow detachment of the retina in the lower part. There was no history of injury. The patient had a cystic goitre and she stated that she was taking some brownish tablets which had been prescribed for the latter condition. These proved to be thyroid tablets. She was advised to discontinue the treatment. Complete rest in bed was ordered, local treatment consisted of six injections of hypertonic saline (five per cent.) at intervals of a week. The vision gradually returned and at the end of six weeks the vision was 6/9 with correcting lenses.

Case II.—Mrs. S., aged thirty, suffering from pulmonary tuberculosis, was referred for treatment of a persistent form of keratitis. Having had previous successes with the use of thyroid in various forms of interstitial keratitis her medical adviser had prescribed small doses of this substance but without beneficial result. This treatment was discontinued, and she was put on calcium lactate, ten grains three times daily, and one per cent. atropine sulphate drops locally. The corneal condition cleared up within a month. She gained weight and her pulmonary trouble was considerably alleviated.

Myles Standish (3) collected eight cases and reported three of retrobulbar neuritis with central scotoma following the use of thyroid extract. The symptoms were loss of weight, general nervous disturbances, muscular weakness, sleeplessness, deficient vision, in both eyes to 6/60 or less. Investigation of the histories showed that in one case as many as nine tablets were consumed daily.

Ophthalmoscopically the signs noticed were hyperemia of the discs without inflammation, venous stasis in the retinal vessels, pain on pressure on the globe together with absolute central scotoma.

In all cases the symptoms improved when the thyroid was discontinued. According to Birch Hirschfield and Inouye (4) in the case of experiments on dogs the anatomical changes found were degeneration of the ganglion cells of the retina with secondary degeneration of the optic nerve fibres.

This form of toxic amblyopia bears clinical resemblance to the variety produced by tobacco, and responds to the same methods of treatment. It is necessary, therefore, in the administration of thyroideum siccum to watch for symptoms of intolerance in susceptible patients.

TREATMENT OF SYPHILIS WITH AMINOARSENOPHENOL OF POMARET

By B. Sherwood-Dunn, M. D.,

Nice, France,

Officier d'Académie, Member Correspondent Société Obstétrique et Gynécologique de Paris.

New remedies, coming from reliable sources, advanced for the treatment of syphilis, which simplify the methods of administration and show results equally prompt and efficacious as the standard preparations already accepted, merit our careful consideration.

Jeanselme, of the Paris Faculty, is a recognized authority, and in conjunction with Pomaret has recently expressed his warm interest in a new arsenical product, aminoarsenophenol, or 132 of Pomaret, now introduced into commerce under the name of Eparseno.

Pomaret's preparation is the aminoarsenophenol of Ehrlich (base, or active body of all the arsenobenzol or novarsenobenzol compositions) but an aminoarsenophenol made stable and soluble in an organic alkaline medium. It is a brown, syrupy liquid containing forty per cent. arsenic, twice as much as is ound in neosalvarsan and other similar preparations. Rabbits have supported a dose by intravenous injec-on of 0. gr. 15-0 gr. 16 to the kilogram of weight, nd mice weighing twenty to twenty-five grams, a ose of six to seven milligrams injected under the kin. It, therefore, is not more toxic to these ani-als than the other arsenobenzols. It is a prepara-on of marked stability, remaining unaltered at a tem-erature of 70° C., which permits its being sterilized y heat. It is prepared in ampoules, ready for intra-uscular injection without the addition of either nalgesic or anesthetic.

The experimental researches of Jeanselme and Pomaret have shown: 1. The spirillicide action and herapeutic efficacy of the aminoarsenophenol, in the pirilla of fowls and experimental syphilis of the abbit. 2. Its comparatively feeble toxic action. 3. ts innocuousness by injection into the muscle or into e veins.

Dr. E. Lepinay, of Casablanca, has published (1) résumé of his observations in the treatment of irty-three cases of syphilis, in both black and white atients, with the express purpose of determining e value of this new preparation. Eight of these ubjects were intolerant of the arsenobenzols. Sixty-ight intravenous injections were administered and 90 intramuscular. In all of the cases but one, the njections were perfectly well supported; in one case, venty minutes after the second intravenous injec-on, the patient was seized with a nitritoid crisis, ith chill, congestion of the face, trembling, tachy-ardia, epiphora, thoracic constriction, etc., all of hich at once disappeared following a hypodermic f adrenalin. The patient was one that had shown ntolerance to novarsenobenzol. Later this patient upported, without any untoward symptom, the in-amuscular injection of a dose as high as twenty-five gm. of the remedy, and at the writing of this report as undergoing his second series of injections.

By intramuscular injection eparseno is used as it omes in the ampoule, without any other prepara-on. The injections are made by preference in the rea of the thigh muscle and are fairly deep. The rimary dose was usually one centimetre cube, fol-owed three or four days later by a dose of two cen-metre cube, repeated regularly every four days. number of the patients were given without inter-uption from twelve to fourteen injections in from orty-five to sixty days forming a total dose of from .80 gr. to 3.50 gr. of eparseno, corresponding to rom 5.75 gr. to 7 gr. of novarsenobenzol. After a elay of from three weeks to one month, some of ese patients were put upon a second series of njections.

The injections were universally well tolerated and ave rise to little if any pain. A certain number of atients complained of a burning sensation at the oints of the piquer and some complained of a sense f swelling. This sense of discomfort invariably isappeared within a few moments, and in only one r two cases did it persist as long as two hours. In o case did it prevent the subject from walking, and ll were able to continue almost immediately their everal occupations. No injection was followed by ny signs of local area of induration.

No fixed hour was selected for giving the injec-ons; they were given morning, afternoon, and evening; before and after meals. In no case was intolerance shown to this remedy, and in only a few of the cases was any elevation of temperature observed and never more than to the extent of a few tenths of a degree, six or eight hours after the injection. Some of the patients complained of cerebral congestion and headache; in two of the cases of secondary syphilitic manifestations these symptoms were particularly accentuated a few hours after the first two injections of 0. gr. 125 and 0. gr. 25 made three days apart. After the second injection these troubles disappeared. In none of the cases was there observed any change in the pulse, respiration, or arterial tension.

The absorption and diffusion of the eparseno throughout the system are extremely rapid if one may judge by its elimination through the urine. Within one hour after the injection arsenic is discovered in the voided urine. The azoreaction is strongly positive in the first urine voided, diminishing in intensity as the day progressed, but was still evident in tests made twenty-four, forty-eight and sometimes seventy-two hours after the injection. It would appear, therefore, that the intramuscular administration of aminoarsenophenol is retained for a longer time in the circulation than after its intravenous introduction, and without apparent accumulation; it is much more slowly eliminated. In none of the urinary tests was there ever discovered any albumin or glucose, and no clinical reaction was ever shown in the liver. In common with all arsenical preparations, the administration of this remedy is generally followed by an increase in the appetite, weight, and general strength.

After the completion of a second series of injections, separated only by one month of rest and consisting of five, six, and seven grams of eparseno, corresponding to ten, twelve and fourteen grams of novarsenobenzol, no evidence appeared in any of the patients of intolerance to the remedy or of arsenical saturation. Eight of the subjects treated were intolerant of intravenous injections of novarsenobenzol, as shown by nitritoid crises and evidence of shock, and one of these patients was intolerant of the eparseno by intravenous injection, but together with the other seven, supported perfectly the introduction of eparseno by the intramuscular route equally large and larger doses than those that gave rise to the prohibitive manifestations by the intravenous route. All were subjected to the completed series of injections and some have been placed upon a second series.

The therapeutic results following the administration of this remedy are clinically identical with those of salvarsan, neosalvarsan, or 102. The treponemas have disappeared from the chancre after the second injection of 0. gr. 25, and in one case after a single primary injection of two centimetre cube (0. gr. 25), proof of the evidence that 0. gr. 25 is required to bring primary syphilis under control; after the second injection the aspect of the chancre is modified and cicatrization commences, and in general is definitely completed in from eight to fifteen days, following the extent of the lesion.

The patients treated presented all the different phases of the malady: mucous patches, papulous syphilides, squamous syphilides, crusts, syphilides palmair and plantair, hypertrophied papulous syphilides, with erosion and other manifestations generally termed tenacious, permitting a clear observation of the evolution of these signs following the treatment.

The treponema found in the mucous patches of one of the patients disappeared the fourth day after the second injection of 0. gr. 25. In some of the cases the roseola disappeared after the first injection, but more often after the second injection (0. gr. 37). The mucous patches became dry and the papulous or the papuloerosive syphilides were reabsorbed after the second or third injection (0. gr. 37 to 0. gr. 62). The papulosquamous syphilides and those with crusts as well as the palmar circinate syphilides become bleached after the third or fourth injection.

The action upon the cephalalgias and the astralgias and the ostalgias were immediate; the pains completely disappeared after the first or second injection.

It was found that the action of eparseno showed rapidly in tertiary syphilis. From the first injections the tuberculous syphilides commenced to disappear and the tuberculous ulcerous syphilides, as well as the gummary ulcers, were modified and commenced to cicatrize. The time necessary for complete cicatrization depended upon the extent and depth of the lesions, but all of them were progressively and rapidly cured. One case of tabes that was intolerant of novarsenobenzol supported perfectly without reaction six injections of 0. gr. 25 repeated every four days.

The Wassermann tests showed little if any deviation from the well established results following the employment of salvarsan.

The commercial introduction of this remedy is too recent and the number of clinical observations recorded are hardly sufficient to place a definite value or appreciate the length of time to which the cures may extend, but from the published reports the following conclusions may be drawn.

CONCLUSIONS.

1. Eparseno is an arsenobenzolic preparation, twice as rich in arsenic as similar preparations and has shown itself to be no more toxic.

2. Therapeutically eparseno has shown itself to be fully as efficacious as any of the other known remedies for syphilis at all of its stages, and in any and all of its manifestations, and possesses the advantage of simpler and less technical application by intramuscular injection.

3. The intramuscular injection of eparseno shows an equally rapid action in the control of all the syphilitic manifestations to any of the other remedies employed intravenously.

If the prolonged use of eparseno confirms the good results already obtained and shows a permanency of effect equal to that of the other remedies at present employed, it will permit of the introduction into the organism of a much stronger dose of arsenic in a smaller volume which must certainly guarantee, therapeutically, a much more powerful assault upon the malady than is permitted by the intravenous route, and it would seem to promise to minimize the risks and accidents that have attended arsenical medication.

It seems to give reasonable promise of the application of arsenotherapy in those cases which are intolerant to intravenous injection and will greatly simplify the use of arsenic in the treatment of this dire malady.

Treatment of Suppurative Otitis Media With Small Perforations in the Ear Drum.—Theodor v. Liebermann (*Weiner klinische Wochenschrift,* March 15, 1923) states that enlargement of the perforation in the ear drum does not aid in drainage or in admitting medication to the Eustachian tube. The treatment as carried out by the attending physician is as follows: In order to have the medication reach the Eustachian tube, the olive of the Politzer bag is fitted to the external auditory canal after it is thoroughly cleansed and the patient is instructed to swallow several times in order to produce variations in the pressure and allow the medication to reach the Eustachian tube, no matter how small the perforation in the drum may be. In order to make this overpressure also available to the patient for selftreatment, he is instructed to irrigate the ear with three per cent. boracic acid solution and then to fill the auditory canal with three per cent. hydrogen peroxide solution by means of a ball ear syringe, the canal being immediately compressed with the end of the finger or the tragus until either a slight attack of vertigo is felt or the medication is felt to trickle into the pharynx. The act of swallowing aids this procedure. In advanced cases without swelling, the peroxide solution may be immediately mixed with three per cent. boracic acid alcohol or a five tenths per cent. alcoholic salicylic acid solution. To remove the swellings in the Eustachian tube alcohol has been recommended, but the author prefers alcohol only when the secretion is slight in amount. In fresh cases he prefers the use of adrenalin preparations to relieve the swelling, after which he uses the medication indicated. With large prolapses, he applies locally such caustics as silver nitrate, solutions of chromic or trichloracetic acids, or the galvanocautery.

Treatment of Cerebrospinal Meningitis.—Jose de Toledo Piza (*Annals Paulistas de Medicina e Cirurgia,* July-August, 1921) gives the treatmen which is used in Brazil. In a suspected case of cerebrospinal meningitis, a lumbar puncture should be done and if the fluid is turbid there should be administered antimeningococcic serum regardless of the bacterial examination. This gives the double advantage of avoiding the inconvenience of later puncture for serum treatment, and of instituting treatments a once. The prognosis depends upon an early diagnosis and the method of utilizing the specific serum which should be injected intraspinously in quantitie somewhat less than the fluid removed from the spina canal, but should not be less than twenty c. c Grave cases do well with forty c. c., with a repetition of the initial dose the following day, and twenty c. c every two days until recovery is assured. The same doses may be given either intravenously or intramuscularly; the writer has never had any untoward effects from the intravenous route. Apart from th serum, the only other therapeutic measures are th application of ice bags, the administration of hexamethylamin, and the injection of cardiac supportives

Abstracts from Current Literature

Etiology of Yellow Fever.—Hideyo Noguchi (*Journal of Experimental Medicine,* September, 1922) reports experiments in which guinea pigs were used to determine the duration of the protective effect of an injection of antiicteroides immune serum. The animals were given different quantities of the immune serum and subsequently injected at various intervals with a virulent strain of Leptospira icteroides. Complete protection lasting five days was given with as minute a quantity of serum as 0.002 c. c. per 1,000 gm. of body weight. After this period, however, the immune substance rapidly diminished, and to keep the animal protected for as long as ten days, it was necessary to give 100 times as much, or 0.2 c. c. Therefore for a man weighing 80 kilos, 0.16 c. c. would theoretically be sufficient to protect for at least five days, 1.6 c. c. for seven days, and 16 c. c. for ten days. Noguchi states that this temporary protection may be a valuable antecedent to that furnished by vaccination, since the final effect of the latter cannot be expected until at least nine or ten days have passed.

The Hydrogen Ion Concentration of Joint Exudates in Rheumatic Fever and Other Forms of Arthritis.—Boots and Cullen (*Journal of Experimental Medicine,* October, 1922) determined the hydrogen ion concentration of joint exudates of patients with acute rheumatic fever, which varied from pH 7.27 to 7.42. The fluids from patients with arthritis of undetermined origin varied in their pH from 7.33 to 7.47. All these reactions were slightly alkaline and approximated the normal reaction of blood. The joint fluids of two patients with bacterial arthritis were both definitely acid. The conclusion is offered that since a definitely acid medium is necessary for the liberation of free salicylic acid, and since all of the joint fluids from cases of acute rheumatic fever were slightly alkaline, no free salicylic acid could possibly exist in such joints following the administration of salicylates.

Diazo Reaction and Its Relation to the Leucocyte Content of the Blood.—N. Svartz (*Hygeia,* 34: 869, November 15, 1922) in his efforts to demonstrate a relation between the diazo reaction and the leucocyte content of the blood, made a study of seventeen cases of typhoid, paratyphoid, and pulmonary tuberculosis. In these cases the leucocyte count falls as the diazo reaction becomes stronger and vice versa. There is no absolute parallelism to be demonstrated but it must be admitted that some kind of relation exists between the two. Discrepancies may be accounted for in several ways. The method of taking the blood count cannot be said to be exact, variations in the concentration of the urine, and the effect of various drugs on the diazo reaction may all modify the results. The cases prove, however, that some form of relation exists between the diazo reaction and the leucocyte count. In searching for a basis for this relationship the most plausible explanation would seem to be that as a positive diazo reaction is found in the great majority of cases combined with leucopenia, the reaction might depend on decomposition of the white blood corpuscles. Diazo reaction cannot be demonstrated in the blood serum, but this does not necessarily exclude the possibility of the reaction being due to decomposition of the white blood corpuscles. If leucopenia is considered as a symptom of toxic disturbance of the blood forming apparatus and as having nothing to do with blood decomposition, then of course diazo reaction cannot be considered as having any etiological connection with leucopenia. It is probable that the same factor is responsible for both diazo reaction and leucopenia and at present it is impossible to demonstrate any causal relation between the two.

Treatment of Pulmonary Tuberculosis.—Clive Riviere and W. H. C. Romanis (*Lancet,* March 17, 1923) conclude that chest operations rapidly and skilfully carried out under gas and oxygen anesthesia are remarkably well tolerated by tuberculous patients, much better than preconceived ideas would have suggested. The gas and oxygen anesthesia is preferable to local anesthesia. The authors favor, so far as possible, extrapleural operations rather than the intrapleural division of multiple adhesions. Of extrapleural operations, the stripping of parietal pleura from the deep fascia (pneumolysis) is the simplest and shortest, provided a suitable medium could be discovered for filling the space. It has the advantage that localized collapse can be applied to localized disease, without the necessity of complete lung collapse. Pneumolysis is undoubtedly accompanied by real risk of sepsis. The establishment of an intrapleural pneumothorax is somewhat difficult and not without risk; adipose tissue, as a filling, is difficult to obtain; paraffin is apt to be returned. This latter accident is probably avoided, in threatening cases, by the aspiration of serous fluid, which tends to be formed and to collect round the paraffin in these cases. The efficacy of paraffin replacements is probably reduced by the fact that no such immobilization of the collapsed area occurs as after extensive rib resection. Furthermore, the localization of the collapse is also, probably, less than might be hoped for. For the majority of cases in which operative measures are needed for the collapse and immobilization of an adherent tuberculous lung, a well devised thoracoplasty seems to offer the best results. The operation is less severe, in skilful hands, than might be expected, and the conditions obtained are very favorable for the arrest of pulmonary tuberculosis. The better lung must be scrupulously investigated and the best moment chosen for the operation. A reactivation on the side of operation may be met by further resection of the ribs, but an extension of disease in the functioning lung admits of no amelioration. This operation, if indications and contraindications are strictly followed, is likely to gain a wider acceptance in coming years.

The Epidural Injection of Antipyrin in Sciatica.—Fr. Högler (*Wiener klinische Wochenschrift,* December 14, 1922) reports some very good results from the epidural injection of ten to twenty c. c. of an aqueous solution of from one to four gm. of antipyrin. The injection should not be repeated before two days. If the sciatic pains are limited to the legs, the perineural injection is sufficient, but with pains in the region of the radicles of the sciatic nerve the epidural injection is immediately indicated. The epidural injection is made in the hiatus sacralis, which allows the medication to reach all sciatic nerve radicles. The site of injection is determined as follows: The sacral cornua are palpated and between and below them an indentation is felt, in the center of which a needle 8 cm. long and not too thin is introduced vertically to the axis of the canal. The piercing of the connective tissue membrane covering the hiatus is determined by the lack of resistance. The needle is then turned at an angle of 90°, so that it lies parallel to the sacral canal, and it is then pushed further in this direction for a distance of four to eight cm. There is no danger of injuring the nerve root as the mere touching of it produces pains and defensive movements. If this should happen, the needle is slightly withdrawn and the fluid is injected without danger. The patient is then allowed to lie in a dorsal or prone position for several hours. The knee-elbow position is the best. With anesthesia of the skin the procedure is painless. Neuralgic pains, frequently associated with sciatica, especially in the adjacent regions of the femoral and lateral cutaneous femoral nerves are also relieved.

Mercuric Chloride Poisoning With Recovery.—Funk and Weiss, (*Journal of Laboratory and Clinical Medicine,* January, 1922) report a case of bichloride poisoning with recovery following intensive eliminative treatment, the case being recorded in order to present the functional studies, which include the ureaconcentration test of McLean and DeWesselow. If this test is generally to be adopted the observation made in this paper, namely as to the comparative innocuousness of administered urea, is important.

Generalized Analgesia After Exposure to Some War Gases.—John Auer (*Journal of Experimental Medicine,* February, 1922) reports investigations on cats gassed with dimethylsulfate or chloropicrine in such concentration that death occurred usually within four days. The animals usually showed a marked generalized anesthesia, both superficial and deep, and reacted with no obvious sign of pain to operative procedures such as laparotomy and gentle friction of the parietal peritoneum. The analgesia developed within a few hours after gassing, reaching its maximum in about twenty-four hours. It may persist for six months with dimethylsulfate, while with chloropicrine practically normal sensitiveness was observed seven days after gassing. Auer explains this analgesia on the basis of a general, low grade, tissue asphyxia, which is chiefly of pulmonic origin.

Blood Destruction in Pernicious Anemia.—Winifred Ashby, Ph. D., (*Journal of Experimental Medicine,* August, 1921) carried out this investigation on thirty-three patients with pernicious anemia, not of Group 4, who received Group 4 transfusions, to determine the mechanism by which blood destruction is brought about, by means of studying the elimination of the Group 4 transfused blood. During a series of transfusions while some of the pernicious anemia patients under observation showed at certain times much blood elimination, on the whole, blood destruction was quiescent. From the evidence presented, Ashby believes that there is no hemolytic toxin producing the anemia in pernicious anemia, and that it is a question whether blood destruction is as important a factor in producing this disease as is generally supposed.

Study of Transfused Blood.—Winifred Ashby (*Journal of Experimental Medicine,* August, 1921) concluded from a study in which Group 4 blood was transfused into a recipient of unlike group that the length of time the transfused blood remains in the circulation varies greatly. The elimination does not appear to be a continuous process, but occurs in more or less cyclic crises, which in women are coincident with menstruation.

Angina Pectoris.—J. Pal (*Wiener Archiv für innere Medizin,* Volume vi, No. 1) asserts that angina pectoris is an angiospastic crisis in the region of the coronary vessels and the root of the aorta. This particular excitability and the predispositon to these attacks in these regions are produced by changes (mesaoritis, atherosclerosis at the insertions of the coronary arteries and endocarditis of the aortic valves) or only by functional causes. In the presence of a predisposition to the attacks, psychic disturbances and sensory stimuli (cold and painful stimuli) may affect this zone. The attacks are associated with circulatory disturbances, which are either coordinated and expressed in a rise in blood pressure (pressore vascular crises) or resultant conditions in the heart (cardiac crises). The vasomotor nature of the attacks is evidenced not only by the prompt action of drugs which have an elective vasodilator effect on the coronary region (like caffein, theobromin, atropin, etc.) and the remedies which have a general spasmolytic effect (papaverin, and the entire benzyl series and the nitrites), but also by the effect of heat and particularly that of fever. An effective therapeutic remedy is the ingestion of hot water. Of other remedies, those that can be administered intravenously deserve the preference because of their immediate effect. These include papavrin, novatropin and their combinations.

Generalized Megalocaryocytic Reaction to Saponin Poisoning.—J. Firket and E. S. Campos (*Bulletin of the Johns Hopkins Hospital,* August, 1922) were led to undertake this investigation through observing a peculiar case of extreme anemia in which there was complete aplasia of the bone marrow, together with a new formation in the liver and spleen of myeloid tissue in which megalocaryocytes predominated. In attempting to imitate the picture, they were able to produce a similar condition in rabbits by saponin poisoning. Their study brought out the following results: After intravenous injections of saponin in rabbits the resistance of red cells to this drug does not show any marked change. The red cells of splenectomized rabbits are not different in their resistance of saponin from those of normal rabbits, although they are more resistant to hypotonic salt solution. Saponin is a highly destructive agent for blood platelets both in vivo and in vitro. The intravenous injection of saponin into rabbits produces in the bone marrow hyperplasia, and, simultaneously, numerous diffuse or circumscribed foci of hemorrhage; there is not a true aplasia. As the function of the bone marrow is impaired by hemorrhages and their effects, the spleen, liver, and other organs show a vicarious myeloid foundation. This newly grown myeloid tissue shows an unusually large number of nucleated red blood cells but mainly megalocaryocytes—megalocaryocytic reaction. This reaction was observed in the lymph glands after intravenous injection of saponin in splenectomized but not in nonsplenectomized rabbits, and may be explained as a vicarious function. The megalocaryocytes found in the bone marrow, spleen, liver and other organs of the rabbits injected with saponin, were not all identical in structure. For a good understanding of the pathological changes in the bone marrow, the authors emphasize the fact that it is important to study large longitudinal sections (of almost the whole organ in rabbits) and cross sections of the marrow of several bones.

Apparent Recovery From Hodgkin's Disease Through Deep X Ray Therapy.—P. Jacob (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* May 10, 1923) reports the case of a woman aged thirty years who sought treatment for dyspnea and large glandular masses in the neck, especially on the left side. A subfebrile temperature had frequently been present for about two months. There was cough, but little sputum, and no tubercle bacilli. A very marked Claude Bernard-Horner syndrome was present on the left side, denoting pressure on the sympathetic. Fluoroscopy showed a shadow occupying the upper half of the left pulmonary field; below this shadow, slightly lateral to the pedicle of the lung, was an opaque spot three or four centimetres in diameter. The diagnosis was confirmed by blood examination and histological examination of an excised piece of enlarged gland. Under twelve deep x ray treatments the glandular enlargements almost completely disappeared, and the lung was markedly cleared, though some radiating dark streaks persisted. The symptoms disappeared, though the Claude Bernard-Horner syndrome showed little change. Some doubt exists as to the permanence of recovery, but the favorable early result testifies to the efficacy of x ray treatment in some of these otherwise refractory cases.

Pathogenesis of Celiac Disease.—As a result of the study of the literature and a clinical study of some of his own cases, Reginald Miller (*Archives of Pediatrics,* February, 1923) comes to the conclusion that celiac disease should be regarded not as an organic disease but as a digestive disorder affecting fat absorption. The exact nature of this disorder is more of a moot question: by a process of exclusion he is led to regard some disturbance of the normal function of the bile salts as the most likely factor, and further research will probably add to the evidence in favor of this conclusion.

Observations Upon Cardiac Rheumatism of Childhood.—Martin O. Raven (*Lancet,* February 3, 1923) shows the desirability of prolonged recumbency in every case of cardiac rheumatism and that the earlier this treatment is initiated, the less prolonged it is likely to have to be. Compared with a policy of physical and emotional rest, fresh air and warmth, such influences as climate cannot be taken into much account. Similarly, treatment by drugs, useful though they undoubtedly are—particularly salicylates, digitalis and opium in appropriate cases —is properly regarded only as accessory to a general management on these lines. In the case of poor people, this policy can only be attempted in institutions devoted to that purpose. Rheumatic carditis, owing to the insidious mode of its onset, will never be prevented from permanently undermining the health of children, unless it is by means of notifications brought under the eyes of responsible medical officers in its early stages.

Properties of Certain Colloidal Preparations of Metals.—The physicochemical tests employed by A. J. Clark (*British Medical Journal,* February 17, 1923) indicate that the active principles of some of the colloidal preparations investigated are entirely in the colloidal form; in other cases the active principles were partly in colloidal form and partly in true solution; while in some cases the whole of the active principle appears to be in true solution. The pharmacological tests employed failed to show any marked difference between the action of the colloidal preparations tested and the action of the same substances in true solution.

Diphtheria of the Nose.—Friedrich Göppert (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) emphasizes the fact that positive bacteriological findings do not always prove the presence of diphtheria and also that negative findings do not disprove its presence. The most important diagnostic feature is the typical membrane, though other infections may also produce it. Bloody secretion, though not commonly found, is an important sign. Some of these cases go to the chronic stage. A unilateral atrophic rhinitis, with or without an odor from the nose, should always lead to the suspicion of diphtheria.

Nature of Arteriosclerosis.—Geoffrey Evans (*British Medical Journal,* March 17, 1923) states that the main feature of diffuse hyperplastic sclerosis is a thickening of the intima, accompanied sometimes by hypertrophy of the media. The intimal changes are the essential lesion. Activity of the endothelial cells is largely responsible for the intimal thickening. In this thickening the process of degeneration plays a secondary part; it is only certainly present in the terminal arterioles of the kidney and the smallest vessels of the other organs. The characteristic feature of the lesion is an intense tissue activity, which is the very antithesis of the process of decay.

Rheumatism and Its Manifestations in Children Under Five Years.—Alonzo de G. Smith (*Archives of Pediatrics,* December, 1922) states that the pathology of rheumatism is not characteristic. Rheumatism is rare in children under five years of age and almost unknown in those under two years of age. As seen in childhood it differs from the adult type of rheumatism in the greater frequency of carditis and the associated syndromes. There are no symptoms that are found particularly in children under five years old. The conditions to be differentiated are scurvy, rachitis, syphilis, osteomyelitis, gonorrhea and tuberculosis. The immediate prognosis as to life is favorable in these children.

The treatment should be directed along the lines of

1, prophylaxis; 2, control of the fever and pain; 3, lessening of the arthritis; 4, the prevention of cardiac disease. The importance of proper clothing (flannels) and the avoidance of dampness and climate should be emphasized; also the necessity of tonsillectomy (where necessary) and the significance of socalled growing pains, restlessness, night terrors and habit spasms. Salicylates control both fever and pain, sodium bicarbonate being added to allay gastric irritation, or they may be given in starch enemas. Locally, the joint is wrapped in cotton, or lambs' wool soaked in lead and opium water, belladonna liniment, or it is rubbed with oil of wintergreen. Splints may be necessary. No drug will prevent cardiac involvement, but prompt and prolonged rest in bed is most important. The heart should be examined daily for signs of pericarditis. When present, icebags, cupping, blisters, leeches, and aspirations are indicated. After the attack has passed off, salicylates should be administered for periods of five to seven days in each month. The aftercare includes the administration of a suitable diet, Fowler's solution, iron and codliver oil. Suitable graduated exercises under direction will strengthen the myocardium.

Pathogenesis of Spasmophilia.—Richard Lederer (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) advances the following working hypothesis in regard to the pathogenesis of spasmophilia: The infantile form of spasmophilia is a constitutional anomaly, produced by a primary disturbance of the balance of the free alkali and earthy alkali ions with a marked preponderance of the former and lessening of the latter. The changes in the hydrogen ion concentration of the blood, body juices and tissues and the appearance of toxic metabolic products (amino bases, etc.) are produced thereby only secondarily. The question whether this disturbance of ionic balance is produced by the loss of parathyroid function or the disturbance of several endocrine glands remains unanswered and naturally pushes the investigation a step further back.

Roseola Infantum.—After studying a series of sixty cases of roseola infantum, H. O. Ruh and Justin A. Garvin (*Archives of Pediatrics,* March, 1923) describe roseola infantum as follows: This disease is a noncommunicable febrile disturbance of unknown origin occurring in infants and young children, having no complication and terminating by crisis in three to five days, following which there appears a rubellaform rash. The majority of their cases occurred in the late spring. The age incidence is usually from six months to two and a half years, rarely up to fourteen years. The period of incubation is unknown; the period of invasion is three to five days. Its onset is abrupt, usually with a temperature of 38.5° C. The temperature rises to 39° C. to 40° C., rarely as high as 42° C., with irregular remissions. In spite of the fever, the patient does not appear alarmingly ill, irritability and a poor appetite being the chief accompaniments of the fever. Usually on the fourth day of the disease, or sometimes as early as the third or as late as the sixth day, the temperature drops by crisis to normal or subnormal. The rubellalike rash appears within a few hours on the neck and spreads to the face, trunk and extremities; it usually becomes less marked as one proceeds toward the periphery. It is papular and maculopapular up to pea size, usually discrete, pale red, not blotchy and it does not itch. It reaches its maximum in twelve to twenty-four hours and disappears within forty-eight hours, leaving no pigmentation or desquamation. The mucosa over the fauces, tonsils and pharynx is reddened. There is no adenopathy. The blood shows leucopenia and relative lymphocytosis. The prognosis is good. During the febrile period the differential diagnosis from scarlet fever, measles, rubella, influenza and variola may be difficult.

Injection of Alcohol in the Treatment of Prolapse of the Rectum in Infancy and Childhood.—Leonard Findlay and J. B. Douglas Galbraith (*Lancet,* January 13, 1923) perform their operation under full anesthesia and the lower bowel emptied by an enema. The prolapse is reduced. With the finger in the rectum to act as a guide, 1.5 cm. of absolute alcohol are injected on each side into the perirectal tissue at a depth of 2 to 2.5 inches. The needle of an ordinary exploring syringe is inserted on each side about one quarter of an inch from the anal margin. The needle punctures are sealed with collodion, a pad is placed on the perineum and kept in position by strapping the buttocks firmly together. The child must be allowed to move the bowels only while in the recumbent position, the feces escaping by the side of the dressing. The pad and strapping are reapplied daily for a week.

The Wassermann Reaction.—Barton F. Hauenstein (*Bulletin of Buffalo General Hospital,* April, 1923) concludes: 1. That the Wassermann reaction with the Kolmer antigens, while the procedure is more complex, is superior to the older methods. 2. By this method the specificity of the test is increased, while the nonspecific complement binding factor is greatly diminished, the weak or doubtful positive results being thus reduced to a minimum. 3. The Kahn precipitin test, judging from the little experience with it, cannot replace the Wassermann reaction.

Idiopathic Priapism.—James C. Sullivan (*Bulletin of Buffalo General Hospital,* April, 1923) reports a case of priapism which was apparently produced by a tonic contraction of the ischiocavernosus muscle. The thrombosis of the corpora cavernosa, although it helped to maintain the erection, must be considered as a secondary event, since the emptying of the clots only temporarily relieved the situation, and not until all the fibres of the muscle were severed could permanent relief be effected. The original cause of the priapism was not determinable. Leukemia, syphilis, disease of the central nervous system and trauma were not present. The past history was absolutely negative. This is a rare condition.

Simple Test for Sugar.—John Livingston (*British Medical Journal,* May 6, 1922) reports that a drop of urine containing sugar evaporated on a glass slide over an alcohol flame leaves a socalled tacky glistening film of syrup. Further heating produces a rich golden color and full heating converts the deposit into burnt sugar or caramel. Urine containing fourteen grains of sugar to the ounce gave the reaction after a five fold dilution with water.

The Relationship Between the Pancreas and e Neuroses.—F. Pineles (*Wiener Archiv für nere Medizin,* Volume vi, No. 1) states that ner- us disturbances of the heart (anxiety, cardiac ins, pseudoangina and tachycardia) are associated ider certain conditions with copious fatty stools, imentary glycosuria, emaciation, Loewi's pupillary action, etc. Inasmuch as the latter point toward disturbance of the function of the pancreas, the sumption of a pathogenic relationship between the sturbances of the heart and the pancreas seems asonable. In the same way do many of the factors patients who belong to the socalled Basedowoid trumous neuropathy) and the patients who suffer ith socalled nervous diarrheas speak in favor of a ose pathogenetic relationship of these symptoms ith the pancreas.

Syphilis With a Negative Wassermann Reac- on.—C. Morton Smith (*Boston Medical and Sur- cal Journal,* August 23, 1923) groups cases of iown syphilis which yield a certain number of gative Wassermann reactions. These are: 1. Early imary syphilis. 2. Late syphilis, a, latent; b, cases ith sharply localized areas of activity; c, tabes with gative blood and positive spinal fluid; d, late lues mulating malignancy. 3. Early infancy. 4. Late ngenital cases with active skin lesions, periostitis, terstitial keratitis, etc. 5. Certain cases under tive treatment with mercury and arsphenamine. arly primary lesions should yield about ninety to nety-five per cent. of positive results by dark field amination and only a small percentage of positive assermann reactions.

X Ray Examination of the Chest.—Hudson and utton (*Lancet,* March 7, 1923) state that an in- pert opinion on a röntgenogram is valueless and ten misleading. A good röntgenogram of a normal iest shows distinct mottling and hilum shadows hich need not be referable to tuberculosis. A ntgenogram may sometimes demonstrate much ore extensive disease than physical signs reveal, id may sometimes be the sole means by which a agnosis can be made. Röntgenoscopy and rönt- nography are essential before undertaking and iring the continuance of artificial pneumothorax.

Heart Murmurs in Infancy and Childhood.— ohn Lovett Morse (*Boston Medical and Surgical urnal,* September 6, 1923) finds that a systolic urmur in the pulmonary area, that is, in the second id third left interspaces, is common throughout rly life. It is so common that it may be regarded physiological. It is always soft and blowing in aracter and systolic in time. The only condition ith which it might be confused is a congenital sion at or near the pulmonary orifice, but when ere is such a lesion there is often a thrill and e murmur is usually rough, loud and transmitted to the neck and back. The right side of the heart often enlarged and the second pulmonic sound is most invariably weakened, and there are usually her evidences of cardiac disease, as clubbing of the gers, cyanosis, bulging of the precordia and dis- rbances of nutrition. A diastolic murmur in the rtic area without cardiac enlargement is usually inctional. A precordial murmur in an infant unless ainly due to a congenital lesion is generally not organic before the child is four or five years old. Such a murmur does not necessarily indicate organic heart disease. No examination of the heart is complete and no conclusions justified unless the size of the heart, the character of the sounds, the condition of the child, and the intensity of the second pulmonic sound are investigated.

Differential Diagnosis of Acute Abdominal Conditions in Childhood.—James S. Stone (*Boston Medical and Surgical Journal,* August 30, 1923) emphasizes both the importance of a history in these cases and the difficulty of obtaining it. A point of value in differentiating abdominal muscular spasm of thoracic conditions from that of abdominal conditions is that in the former palpation of the abdomen has a tendency to relax the spasm, while in the latter spasm increases as the muscles attempt to prevent pressure on a tender spot. Conditions to be thought of and differentiated are appendicitis, pyelitis, enlarged mesenteric glands, Pott's disease with girdle pains, and tuberculous peritinitis. Obscure abdominal lesions with a low white count and a positive Pirquet reaction are likely to be tuberculous peritonitis. Intussusception is the great surgical emergency in infancy, and here fortunately the symptoms are characteristic, namely, sudden onset with pain and shock; pallor, cold sweat, reflex nausea or vomiting; mucus, bloodstained mucus, and then blood in the stools. A painstaking history taking may eliminate many conditions even before the child is seen. Then see everything that can be seen, and feel everything that can be felt, including what can be felt in the pelvis by rectal examination. When the examination is finished, consider the whole picture and the history. Then will come the need for laboratory aids, white cell count, Pirquet, urinalysis, and x ray. The latter is of value in certain cases but sometimes involves dangerous delay and harmful manipulation.

Isolation of White Blood Cells.—Paul Szilard (*Journal of Laboratory and Clinical Medicine,* July, 1923) reports in detail a simple method whereby white blood cells can be isolated almost quantitatively from a small volume of blood. The essential point of the procedure is the destruction of the red blood corpuscles and the thrombocytes in a manner which will leave the white cells unimpaired. In a mixture of acetic and tartaric acid the while blood cells scarcely suffer at all. The solutions used are a 2.5 per cent. solution of acetic acid; two per cent. solution of tartaric acid; two per cent. solution of potassium hydroxide, and Locke's solution. The acetic and tartaric acids are used for hemolysis. The acid mixture is poured quickly into the blood until hemolysis takes place. The quantity of alkali necessary to neutralize the acid mixture to phenolphthalein is determined, and for each ten c. c. of blood one c. c. more than the quantity of alkali required for neutralization is used. The alkali is poured rapidly into the tube and well mixed, and the tube centrifuged for not more than five minutes, at not more than one thousand to fifteen hundred revolutions per minute. After centrifugation the supernatant fluid should be poured off and the sediment suspended in Locke's solution and washed with it once or twice at a low speed of the centrifuge.

NEW YORK, WEDNESDAY, OCTOBER 17, 1923

Insulin Treatment.—Irvine H. Page (*Journal of Laboratory and Clinical Medicine,* July, 1923) used the Benedict-Osterberg normal urine sugar method for his determinations. Samples of urine were collected hourly from 7 a. m. to 7 p. m., and the combined twelve hour night specimen was saved. The results on the normal persons indicate, on a statistical basis, that the curve of normal sugar excretion is remarkably constant, but with a slight upward trend from morning to evening, with a low level during sleep; considered on the basis of hourly samples, the quantity of sugar excreted rises for one hour after meals, then sharply falls (the original on a lower level). The rise in no way depends on the quantity or quality of food ingested. In general the greatest rise follows breakfast; the curve of the socalled normal cases does not go above the 90 to 110 mg. level. Great variations and remarkable constancies of sugar excretion may occur at different times in the same person. In the borderline and suspected diabetics there was a remarkable ability to maintain a sugar free urine except two to four hours a day. These socalled breaks usually occurred one and one-half hours or longer after meals and may last for one to two hours. The author believes that the ability to detect latent, borderline or mild diabetics depends on the determination of the picture of hourly sugar secretion, under the varying conditions of the patient's life. He thinks the test described is superior to the glucose tolerance test, as on one hand it detects abnormally high sugar wastage, and on the other warns of dangerously low sugar secretion, hence offers an ideal method for the control of cases under insulin treatment.

Treatment of Tuberculosis.—Robert Philip (*British Medical Journal,* March 24, 1923) believes in the superiority of the percutaneous over the subcutaneous method of administering tuberculin. He found that tuberculin is freely absorbed when it is rubbed firmly into the skin and that it exerts a specific influence on tuberculous processes throughout the body. The therapeutic effect is noticed very soon. The other advantages of this method of administration are the absence of pain and discomfort, the procedure is not dreaded, especially by children, and it is, to a certain extent, a gauge of the susceptibility of the patient, which in turn determines the amount and frequency of the dosage. The therapeutic effect on superficial tuberculous lesions (cutaneous, glandular, etc.) becomes apparent within a few weeks and is usually continuous. The author favors this form of treatment as early as possible in the chronic glandular enlargements in children, thereby favoring the prevention of deeper involvement. The actual amount of tuberculin, if it is used in twenty-five per cent. dilution, is about 0.1 c. c. in an ointment base, which is rubbed in a sterilized area of skin measuring about one or two square inches.

Treatment of Syphilis.—Nicolas V. Greco (*La Semana Medica,* August 2, 1923) summarizes his article as follows: 1. Zinc has proved efficient in all three stages of syphilis in clearing up subjective symptoms. 2. In the primary stage there was noted lessening of infiltration of the chancre and reduction of glandular swelling. 3. In the secondary stage it caused a disappearance of the rash, but had no effect on mucous patches, in fact seemed to favor their appearance. 4. In tertiary lues it cleared up cutaneous gummata and periostitis. 5. Zinc exercises a tonic reconstructive action on the system. 6. Zinc may be combined with mercury in any case where iodides are indicated. 7. The dose is about that of the corresponding mercurial salts and the toxicity is not a factor in the medicinal dose.

Treatment of Pneumonia.—H. T. Nippert (*Minnesota Medicine,* September, 1923) believes in the isolation of the patient, the disinfection of linen and secretions. Ether pneumonia may be reduced by shortening the duration of the anesthetic and by substituting local anesthesia where possible, particularly where patients have colds, diseased tonsils or infected sinuses. United States Public Health Service reports show very little benefit from prophylactic vaccination. The patient should be kept warm and comfortable and not allowed to become chilled. An initial dose of calomel followed by magnesium citrate is advisable; plenty of water is indicated, especially if the toxemia is progressive; to the water may be added the acetate, bicarbonate and citrate of potassium to increase diuresis. An entero- and hypodermoclysis of normal saline solution or the intravenous injection of 250 c. c. of ten per cent. solution of glucose will assist elimination. Alcohol is valuable. Venesection in the plethoric, eight to sixteen ounces, will often relieve dyspnea. Fever as a rule will take care of itself; pain must be relieved by opiates; quinine fifteen to twenty grains as an antipyretic is referable to depressing coal tar products. Edema of the lungs calls for venesection in suitable cases, or the use of atropin or oxygen. The patient should be kept in bed at least a week after his crisis. X ray examination is of service especially in localizing an empyema or a lung abscess. As to blood pressure, Gibson's rule that when the pulse rate per minute is higher than the blood pressure in m. m. of mercury the prognosis is less favorable.

Treatment of Pyelitis by Ureteral Catheterization and Instillation of the Kidney Pelvis

By JOHN COOKE HIRST, M.D.,
Philadelphia, Pa.
Gynecologist to Mt. Sinai and Philadelphia General Hospitals.

Until a comparatively few years ago pyelitis was rarely diagnosed as such. Many chronic cases were diagnosed as appendicitis and entirely needless operations were done, naturally without relief. Acute cases were diagnosed as various acute inflammations of the kidney proper, of the intestine, or the appendix, and the real nature of the infection was entirely unsuspected. Now, however, with our knowledge of the disease, mistaken diagnoses are uncommon and usually the result of carelessness and lack of study of the patient.

INFECTING AGENT.

The bacteria causing the infection may be any of the pathogenic bacteria, but the vast majority of cases are due to a bacillus of the colon group, either the colon bacillus itself or its very close relative, the Bacillus aerogenes mycosum. Those due to other bacteria are so rare as to be practically negligible, and need hardly be considered.

SYMPTOMATOLOGY.

Symptoms of the attack in the acute cases are: fever; relatively high leucocyte count, often over 25,000 and with a high percentage of polymorphonuclears; pyuria, usually to the extent of cloudy urine, though not always; and pain in the lumbar region on the affected side. The right side is much more commonly affected than the left, especially in pregnancy (when the pressure of the pregnant uterus on the ureter at the pelvic brim is a predisposing cause), but the left side is quite often involved, and at times the infection is bilateral.

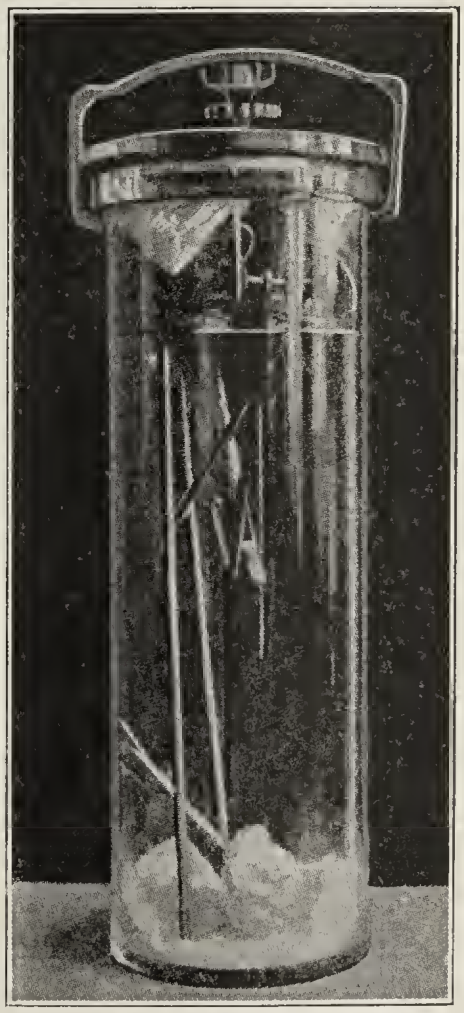

FIG. 1.—Sterilizing plant for cystoscopes and catheters. Loose formaldehyde powder in bottom of jar. Efficient and inexpensive.

The chronic cases are due either to the persistence of an acute infection, or else begin with an infection so mild as to be free from the symptoms of the acute attack, and run a chronic course from the very outset. Occasionally, the acute attack closely simulates an acute intraabdominal infection, and for the first twenty-four hours the differential diagnosis may be a matter of extreme difficulty.

POINTS OF PAIN.

Pain in the affected lumbar region is a constant symptom in the acute cases, but a variable one in the chronic. It is a constant, dull ache, with exacerbations of quite acute pain, and is always intensified by bimanual pressure. The second point of tenderness is where the ureter crosses the pelvic brim, and this is often quite acute under pressure. It is this point that is responsible for the multitude of mistaken diagnoses of appendicitis, as the site of the ureter crossing the brim is almost directly under the appendix. It would not be going too far to insist that no woman should be operated upon for chronic appendicitis until she has been cystoscoped and pyelitis excluded. The third point of tenderness, often overlooked, is where the ureter enters the bladder. This is usually elicited by vaginal palpation only and is not a subjective symptom. In cases of long standing the ureter can often be felt like an indurated cord, through the vaginal vault, though in such a case tuberculosis is to be suspected.

The true diagnosis is usually easily established by the above mentioned symptoms alone. In any case

Copyright, 1923, by A. R. Elliott Publishing Company.

of doubt, the patient should be cystoscoped, and the triangular area of erosion, with its point at the ureteral mouth and its base in the trigone, can easily be seen. In addition, a few minutes' watching will show the ureter spouting cloudy urine. In any case where actual thick pus is seen slowly to exude from the ureter, tuberculosis is to be suspected. In ordinary pyelitis the urine is simply cloudy, or at times even milky in appearance.

TREATMENT.

The palliative treatment of pyelitis is usually a waste of time. Rest in bed; milk diet; plenty of water; bladder irrigation with boracic acid solution to increase ureteral peristalsis and hence drainage; ice bag to the affected lumbar region; urotropin or other urinary antiseptics, practically exhaust the means at our command. I much doubt whether they have any influence at all on the course of the infection, and believe that, with the usual tendency of human ailments to selflimitation, the case would pass into the subacute or chronic stage as quickly if no treatment other than rest in bed were instituted. At the most optimistic outlook, palliative treatment cannot cure the infection, but merely bridges over an interval, often days long, until the patient establishes her own immunity or antitoxin, if the term can be used in this connection. I have long since discarded the palliative treatment and would advise it only where lack of the necessary instruments or training in their use prevents carrying out the rapidly effective active lavage and instillation.

ACTIVE TREATMENT.

This consists of catheterization of the ureter and instillation into the pelvis of the kidney of eight to fifteen c. c. of a solution of silver salts, which will be described below.

Of the two methods of cystoscopy, involving distention of the bladder with air or water, the water distention is in much more common use, and much to be preferred. It can be done, in chronic cases, as a routine office procedure, without difficulty or pain, and involves no such uncomfortable position of the patient as is needed in the air distention method. In addition, proficiency in its use is infinitely easier to acquire. A short description of the technic I have found thoroughly satisfactory and least troublesome may prove of value.

1. The patient is placed in the ordinary dorsal position, as for any other vaginal examination.

2. A four ounce metal funnel (glass cracks too easily in boiling), to which is attached a fairly large calibre rubber catheter, is prepared by boiling (Fig. 2).

3. This catheter is anointed with a solution of ten per cent. cocaine in glycerin, acting not only as a lubricant but as a local anesthetic.

4. The catheter is inserted into the bladder, after proper preliminary cleansing of the vestibule and urethral orifice. Any urine in the bladder is drained off.

5. The bladder is filled with cold sterile water, to the point of tolerance of the patient. She should be impressed with the need for cooperation on this point. The commonest points of difficulty are too little water in the bladder and too dim a light on the cystoscope. The reason for cold water in the bladder is to minimize softening of the ureteral catheters to be used and making their introduction easier.

6. The cystoscope, with catheters in their channels, is inserted and the light turned on. The ureters are usually easily found by turning the cystoscope, with the lens facing the trigone, at an angle of 45° to the middle line.

7. If the ureteral orifice cannot be found, the difficulty can easily be overcome by injecting intravenously two c. c. of indigocarmine solution. This procedure is entirely harmless, and in two and a half minutes blue urine will spout from the ureters, as against twelve to fifteen minutes when it is injected intramuscularly. This makes the ureteral orifice easily seen, and it can then be catheterized. With moderate practice, however, this method is rarely needed.

8. The infected ureter is catheterized and the catheter pushed in as far as possible, up to the kidney pelvis. If difficulty is experienced in getting the catheter to travel up the ureter, it can often be overcome by rolling the catheter in the fingers, at the same time pushing it upward. Frequently smaller sizes must be tried before the kidney pelvis can be reached.

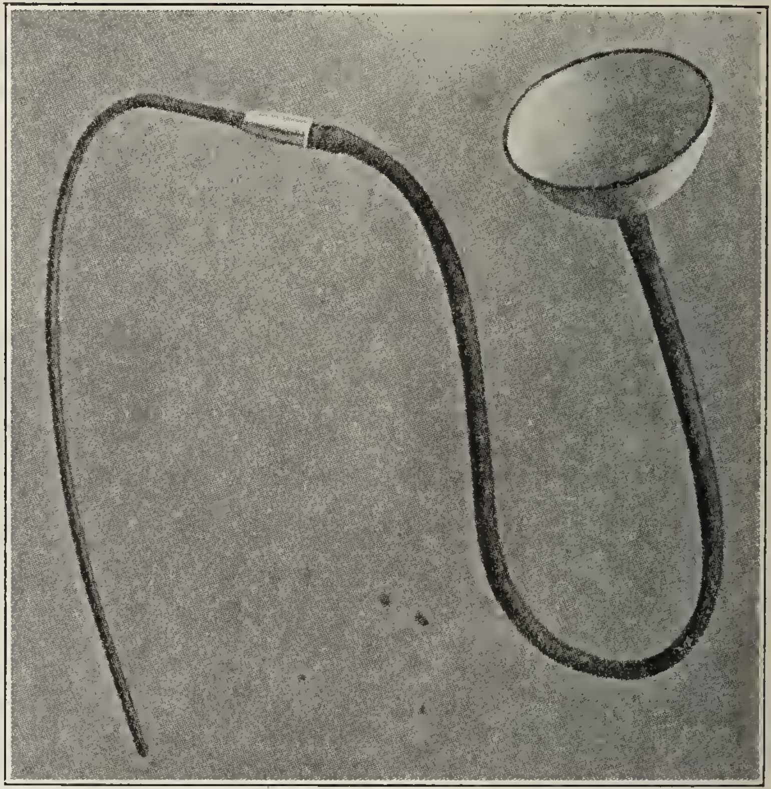

FIG. 2.—Apparatus for irrigation of the bladder, consisting of a catheter, glass connection, rubber tube and a metal four ounce funnel. A glass funnel is too likely to crack in boiling.

9. Through the catheter eight to fifteen c. c. of silvol or neosilvol solution, ten per cent., are injected slowly and without force. This is the capacity of the average kidney pelvis. Preliminary irrigation of the pelvis of the kidney with boric acid solution is unnecessary and a waste of time. Should the patient complain of any pain in the back, the injection must be stopped at once. This symptom should always be inquired for, and no attempt ever made to inject the solution forcibly.

10. When the desired amount has been injected the cystoscope and catheter are withdrawn together and the water in the bladder either withdrawn by a catheter or by voluntary expulsion.

No general anesthetic is needed, even in nervous patients. Occasionally the urethral orifice is too small to admit the cystoscope, and must be dilated, st by metal sounds. This can be done practically inlessly, under the local anesthesia of the cocaine lution. The same solution is used as a lubricant the sounds and cystoscope.

There is ordinarily no afterreaction of any kind, that the method can, in chronic cases, be used as outine method of office treatment. In acute cases, th fever and high leucocyte count, the patients are, course, not ambulatory and the irrigations can be rried out either at their homes or in hospital, as y are confined to bed. Rarely, there is acute pain nulating stone in the ureter, of short duration. is is probably due to a small blood clot, caused by passage of the catheter, which at times, by its int, inflicts slight trauma to the ureteral walls.

At times the urine is so cloudy that it is difficult get a satisfactory view of the bladder walls and eteral orifice. In such cases, if the bladder is reatedly filled with sterile water and immediately iptied, a clear field of vision can be obtained after ly a few minutes of this irrigation. It is obvious, course, that if the ureter appears healthy and bladder infected no attempt at catheterization ould be made.

SOLUTIONS USED.

After a trial of many different antiseptic solutions, er a period of a good many years, I am now using per cent. or fifteen per cent. solution of silvol neosilvol in all this work. Silvol makes a dark own solution, staining deeply anything with which comes in contact. Neosilvol makes a milky, yelvish solution and is free from this objectionable ining. I have repeatedly used the fifteen per cent. ution of either one in the pelvis of the kidney, thout evidence of pain or secondary irritation. I itinely employ the ten per cent., however, reving the stronger solution for obstinate cases. It better for the solution to be freshly prepared, ough it will keep for several weeks without eviice of deterioration. My own plan is to renew solution every week, and have prepared only ough to meet my average requirements for that ie. It can easily and quickly be prepared, howr, should more be needed. These two solutions ve given and are giving me better results than I ve been able to obtain with any other, and I have ind them most satisfactory.

RESULTS TO BE EXPECTED.

In acute cases, the rule is an immediate marked provement. The temperature falls, leucocyte int drops, and the patient is immediately more nfortable. Not infrequently one irrigation is all t is needed, but as a rule the treatment must be eated three or four times, at twenty-four or forty-ht hour intervals, governed by the urgency of the nptoms. It is rare indeed for a patient with iple pyelitis to need more than three or four intions all told, and recurrence at a later date is y rare. A case of stone in the pelvis or of tuberosis is of course a different matter, but these are the subject of discussion here. The urine clears promptly, pus disappears, all symptoms subside l the patient is rapidly well. Even in the cases ere one injection seems to be enough to clear up symptoms, I have learned that it is wiser to ret it once or twice to avoid recurrences. To anywho has tried both the palliative and active forms of treatment, the value of the active has been demonstrated beyond all discussion.

PYELITIS IN PREGNANCY.

In pregnancy pyelitis is nearly always acute, or the acute exacerbation of an old chronic attack. It often presents an alarming picture, with high fever, high leucocyte count and milky urine loaded with pus cells. The later in pregnancy the more acute and serious the attack, though the commonest time is from the fourth to the sixth month. It is in these cases, however, that instillation of the pelvis of the kidney gives the most rapid and brilliant results. It is common to see a patient with a temperature of 103° or over, leucocytes 25,000, one or more chills and giving every evidence of severe infection, in whom, after one injection of fifteen per cent. silvol or neosilvol into the pelvis of the kidney, all symptoms will subside, and within twelve hours the patient will be comfortable and apparently well. It is advisable to give two or three more injections, however, to avoid a later recurrence. It is entirely unnecessary to induce labor or otherwise terminate pregnancy in these cases. They are not well equipped at the moment to stand the strain of labor or surgical interference and it is a great mistake to subject them to it. Anyone who has seen the astonishing change produced in these cases by the simple instillation of the kidney of the pelvis would never consider any other form of treatment.

There is a difficulty to be met in these cases, however, that does not exist in the nonpregnant patient, and the later in pregnancy the more pronounced is the difficulty. The trigone of the bladder is greatly congested and the ureteral openings much less plainly visible than in the nonpregnant patient. In the later months the child's head causes a bulge of the bladder in the midline, so that there is a pouch on either side, on the sloping side of which is the ureteral orifice. If an extra amount of water is put in the bladder, and, with the patient in the dorsal position, the foot of the table is raised somewhat, much of the difficulty will disappear, though the process is never as easy as when not complicated by pregnancy.

PYELITIS IN CHILDREN.

This condition is fortunately rare, though cystitis is very common. Should it develop, however, it is perfectly practicable to catheterize the ureter of any female child over eighteen months of age. A specially small, single channelled cystoscope has to be used, and often general anesthesia, as the child is sure to be unruly. The same solution of silvol or neosilvol may be used, though I never use over ten per cent. in children, and the total quantity injected varies from two to five c. c. which is practically sure to fill the pelvis of the kidney.

In these children it is rare to have to repeat the instillation, and it is also inadvisable, because of the need for repeated anesthesia.

INSTRUMENTS REQUIRED.

For many years I struggled along with the usual type of lens cystoscope, with a very limited field in the catheterizing scope. Some years ago, however, a cystoscope of 24 F. calibre was designed by Dr. B. C. Hirst, of Philadelphia, with a wide angle lens and a high power tungsten film lamp. This is known as the Brown-Buerger special and is incomparably superior to the older cystoscopes. The field is large enough to show both ureters at once, and it enormously simplifies the task of catheterizing, besides using the same lens for both simple examinations and catheterization.

Sterilization may be effective in several ways. A metal sterilizer with a lamp vaporizing formalin pastilles is very effective, but has several disadvantages. It is undeniably effective, but the hot vapor softens the catheters and it is difficult to insert them, as they become very limber, and the lamp is forever going out just when it is most inconvenient.

All cystoscopes are now made with watertight lenses at both ends, and therefore cystoscopes, catheters and all appliances can be soaked for an hour or more in a one per cent. formalin solution without injury to them and with assurance of sterility. This solution must be thoroughly rinsed off with sterile water before use, as it is most irritating to the bladder and urethra and also to the operator's eyes, on looking through the eye piece lens.

A satisfactory sterilizer is the one shown in Fig. 1. It is an ordinary pathological specimen jar with a rack for holding the instruments. A thick layer of formaldehyde powder is in the bottom. All instruments and catheters are put in it, and the top screwed on. It serves both as sterilizer and transporting case, and the instruments are kept always ready for use. It has the slight disadvantage of tarnishing the nickel plating of the instrument but does not affect the lenses at all. This tarnishing affects the appearance of the instruments, but does not in the least affect their optical qualities. This small disadvantage is more than offset by the greater advantage of ease of transportation, protection and constant sterility.

After use the instruments must be thoroughly dried; the catheters being cleaned and dried by forcing them first through sterile water, then ninety-five per cent. alcohol, and then ether. They can be kept in good condition only by keeping stylets constantly in them, for their entire length, when not in use. At best their life is short and when once they become rough or limp should be discarded. The stylet should be of German silver, as the ordinary wire one will rust and rapidly spoil the catheters.

1823 Pine Street.

The Surgical Treatment of Puerperal Infection

By HENRY B. SAFFORD, A.B., M.D., F.A.C.S.,
New York.

There has been great advancement in surgical technic, methods, and systems during the last decade. Methods of precision in relation to asepsis and antisepsis have opened up remarkable possibilities in certain surgical branches. The two notable fields in which lack of progress has been significant are the surgical treatment of cancer and of the infections that still so frequently develop in connection with abortion and confinement.

Statistics of death rates compiled from many sources show that puerperal mortality in this country reaches an annual total of about twenty thousand deaths, at least half of which are due to some form of infection. If these figures represent the mortality rate, it does not require a vivid imagination to compute the enormous number of infected cases from which the statistics were compiled.

The student cannot fail to be impressed by the generally unsatisfactory nature of much of the treatment suggested for puerperal infection, as well as the wide divergence of opinion upon the subject. Thus, one surgeon would subject every patient with a postpartum temperature to a curettage, while another declares this treatment to be pernicious. If a census were taken, it is probable that it would be found about equally divided between those who curette and those who do not.

It is obvious that the habit of universal curettage is not completely satisfactory. In fact, its use rests upon the uncertain and incorrect assumption that there is retained placental material in every case of abortion or confinement in which there is an elevation of temperature. Moreover, it is impossible to scrape the interior of a large uterus entirely clean by the ordinary curettage methods, which are like one clumsily groping in the dark. And if this process does result in the removal of a certain amount of disintegrating material, it is also certain to remove much protective endometrium, open up lymphatic and venous channels, destroy Nature's leucocytic wall and frequently produce a troublesome and alarming hemorrhage, which still further depletes the vitality of the patient at a time when she is most needful of all her powers of resistance. More than this, it is a well known fact that the mortality rate in cases treated in this manner is discouragingly high.

The expectant treatment is quite as unsatisfactory; summed up, it is no treatment at all. The fact that there may be a mass of festering organic material within the uterine cavity is ignored. It is left to rot out, and it will rot out in the course of time, if the patient lives long enough. The patient is allowed supportive treatment while the rotting process takes place. The only surgical principle involved in this system is that of gravity drainage, effected by a modified Fowler posture. The surgical fundamental of safeguarding drainage of cavities from the bottom is neglected. Anyone who has been obliged to watch a patient struggle for weeks and even months under the socalled expectant treatment can feel that the length of the fight might perhaps have been satisfactorily curtailed had some more efficient measure been adopted from the beginning. It would be difficult to prove that the mortality rate with this method of treatment differs materially from that of universal curettage.

The entire field of obstetrical surgery presents a r more difficult problem in reference to asepsis than es almost any other branch of surgery. Not only ust we deal frequently with an unsterile field, but so one in which the resistance has been weakened by olonged traumatism and which, in most forms of fection, does not possess a barrier of the poten- ility of the peritoneum.

ICROORGANISMS CAUSING PUERPERAL INFECTION.

The principal microorganisms which have been own to be responsible for puerperal infection are e streptococcus, the staphylococcus, the gonococcus d the colon bacillus. There are lesser micro- ganisms giving rise to a lower grade of infection, ch as the socalled sapremia. It should be remem- red that some of these bacteria are doubtless being troduced frequently into the vaginal canal of the egnant woman from a number of sources, and e know that they do not immediately become nocuous. In a recent bacteriological examination vaginal secretions from antepartum cases, two owed the presence of the colon bacillus and from anatomical viewpoint it is remarkable that this cillus is not universally present. It can be demon- rated that many vaginal cultures show the presence gram positive microorganisms, both bacilli and cci. Doubtless many of these are nonpathogenic. very vaginal examination, therefore, possesses the nger of carrying infection from the interior, as ell as exterior, higher up into the birth canal to creasingly fertile culture media.

The perfectly normal puerperium should be table for the complete absence of any constitutional mptoms whatever, a rise of temperature usually ing the first sign of trouble. Any case in which e temperature exceeds 100° on any two consecutive daily readings during the first week following de- very should be considered one of puerperal fever d its source carefully sought. The morbidity rate, measured in these terms, will be found high. very physician has frequent cases where there will present a mild fever for two or three days with other constitutional symptoms, the temperature ortly subsiding to normal and the source of the ouble never being accurately determined. On the her hand, when upon the third or fourth day stpartum there is a chill, followed by high eleva- on of temperature and disproportionate pulse rate, situation has presented itself so fraught with dan- r that most energetic measures must be taken.

LOCATION OF FOCUS OF INFECTION.

There are two factors preeminent in the handling a case of puerperal infection—promptness of tion and an accurate diagnosis of the location of e initial focus of the infective process. Both these ctors are difficult to cultivate. Many doctors are luctant to admit, particularly if they happen to ve been the responsible parties in the case from inception, that they have to deal with a case of fection. It is easier to temporize. Other possible planations to account for the symptoms that are coming so alarming present themselves. It may attributed to lactation, constipation, nervousness, alaria, too many visitors, or any other triviality.

It should be possible to eliminate promptly any these possibilities and it seems unnecessary here emphasize the danger of allowing oneself to be ng deluded by one of them. If it can be demonstrated that the cause is outside the generative tract, so much the better, but the burden of proof should rest upon the physician. The proper procedure is to look the proposition squarely in the face that in all probability one has to deal with a case of infection, and then act accordingly, with courage and promptness.

The location of the focus of infection is by no means always easy to discover. It will eventually nearly always manifest itself in some definite lesion along the genital tract. There is, however, one class of primary blood infections which must be differentiated in puerperal cases, as such processes are often blindly treated and a successful outcome depends upon the early discovery of the initial focus. The source of these will be found outside the generative tract in such locations as the teeth, tonsils, breast, gallbladder, liver, pancreas, intestinal tract and the urinary tract, the last named beyond doubt being the most common. In fact, it would appear strange that a larger proportion of these infections do not ascend the urinary branch of the genitourinary system.

The factors limiting infection by the kidney route are, the more circumscribed anatomy of the urinary system, a certain immunity that has been acquired from the proximity of the colon, and the irrigating process of Nature. The symptoms are in many respects similar to those of infection of the internal organs of generation and, should the process develop subsequent to confinement, the diagnosis may be temporarily clouded. When a patient has a chill at about the fourth day following her delivery, together with a sudden elevation of temperature and pulse rate, it becomes highly important to decide at the earliest possible moment whether the infection is of the genital organs or of the urinary system; for if the former, suitable treatment at the earliest possible moment is essential. It is quite certain that patients showing elevation of temperature following childbirth have been rushed to the operating room and curetted, when the lesion itself was in the kidney.

Having eliminated extrinsic foci of infection, a primary focus connected with the genital tract will nearly always manifest itself by some definite lesion along one of four areas, classified as follows:

1. Infection of the perineum.
2. Infection of the cervix.
3. Infection of retained secundines.
4. Infection of the interior of the uterus.

Some of these infections will remain localized and some will spread to other areas very quickly. It is the purpose of prompt and forceful treatment to destroy, or at least to modify the virulence of the infection at its primary focus, before it has invaded adjacent areas and perhaps become a systemic condition which will end fatally.

INFECTIONS OF THE PERINEUM.

Infections of the perineum, as well as of other vaginal tracts, occur, first, in areas which have not been repaired, but have been left open; second, upon the site of a primary perineorrhaphy. It is hardly necessary here to emphasize the importance of a careful examination of the vaginal canal after delivery, with a well adjudged repair of any injuries noted. Tears are of frequent occurrence in other parts of the vaginal canal than the centre of the perineum. The honesty or acumen of the man who never gets a tear are under suspicion. It is certainly an unsurgical procedure to leave a raw, bleeding surface open to invite infection.

Infections following repair are augmented, not only by the fact that one must deal with severely traumatized tissues, but also by the common temptation to draw sutures too tight, thus interfering with the normal nutrition of the part.

Infections of a laceration, whether open or repaired, present practically the same symptoms of toxic absorption. The treatment is the same and aims at checking the spread of the infection while destroying its focus. All sutures must be removed and the torn surfaces should be kept from contact with each other by wet, strongly antiseptic gauze packs, which should be changed frequently. The patient should be put into the exaggerated Fowler posture. Such treatment will nearly always produce quick results if inaugurated promptly after the discovery of the lesion.

INFECTIONS OF THE CERVIX.

These are most serious. The lymphatic supply of the cervix is such that in a neglected cervical tear we have a tremendous port of entry for infection directly to the important lymph channels. For this reason infections of the cervix rarely remain localized, but when discovered are giving rise to such pyramiding types of infection as lymphatic septicemia, where the outcome will be serious.

There seems to be no good reason why these cervical tears should be neglected, particularly in those cases which are handled under proper surgical conditions. Examination of a large number of women after delivery seems to warrant the statement that in practically all primiparæ the cervices are lacerated to a greater or less degree. It is quite true that in a large percentage of these cases the laceration is comparatively slight and may even be undiscoverable immediately after delivery owing to the traumatism to which the tissues have been subjected. On the other hand, in many cases the cervix is widely lacerated, frequently even to the vaginal vault, and it is a fact that rarely are such lacerations even sought for, except in the event of hemorrhage, which drives the obstetrician to an investigation. Good surgery certainly points to the repair of extensive injuries when they occur in any part of the body, thus closing certain patent channels for infection.

INFECTION OF RETAINED SECUNDINES.

It is obvious that fragments of secundines frequently remain in the uterus without the knowledge of the physician. The classical routine examination of the placenta and membranes after the third stage of labor is often treacherous, in that it inspires the examiner with a false confidence.

This class of infection and that covering involvement of the interior of the uterus constitute a very large proportion of the cases of puerperal fever. There is no question that the process is likely to extend from retained placental material to the uterine interior itself. We come now to the proposition of curettage. Shall we curette in all cases with an excessive elevation of temperature, when the uterus is large, soft and sensitive, or shall we leave all such cases religiously alone, waiting for the disintegrating material, when present, to rot out?

It appears unsafe and unscientific to formulate a comprehensive rule for this entire class of cases. It should be possible to differentiate between those in which the uterine cavity contains disintegrating material and those in which it does not. There are two symptoms which commonly occur in the former type of cases, hemorrhage and contractions resulting from the efforts of the uterus to expel its contents. In addition, there is a sure means of investigation by palpation of the interior of the uterine cavity. This may be accomplished with accuracy under a general anesthetic. The ordinary bimanual examination with two fingers will not suffice. The entire hand must be introduced within the vaginal canal, the two examining fingers penetrating the cervix; then, with firm pressure of the external hand upon the fundus the large, soft, open uterus can be sufficiently inverted to allow the palpating fingers to explore all parts of its cavity. Foreign material should be removed by these fingers augmented by sponge, forceps, and not by a sharp curette, for the curette is a blundering instrument which causes new, open wounds of the uterine mucosa, making patent new channels for extension of infection from the already involved secudines. It is certain that if retained material is so firmly adherent to the uterine interior as to preclude its removal by the method described, further attempts through the medium of a sharp curette can only result in extensive excavation of the uterine wall itself.

INFECTION OF THE INTERIOR OF THE UTERUS.

This usually takes place at the placental site. When in a case presenting a large, sensitive, improperly involuting uterus, the uterine cavity has been demonstrated, in the manner just described, to be clear, there probably exists a septic endometritis or metritis, or both. It has been taught upon good authority that there is at present no means of treating primary infection in the uterus which does not at the same time favor extension of the inflammatory process to the surrounding tissues or to the blood stream. It is also argued that local treatment in this class of cases comes too late, as the infection has already penetrated beyond its original focus and is rife as a systemic infection. It is doubtful if these arguments can be sustained by any array of facts and figures.

Carrel demonstrated several years ago what could be accomplished in the treatment of infections by the frequent scientific application of a powerful antiseptic solution. Utilizing the surgical principle involved in his methods, tubes adapted to the proper dissemination of a germicidal solution may be introduced into the uterine cavity. It is best to use two tubes, one long enough to reach nearly to the top of the cavity, the other much shorter. The best solution is undoubtedly some form of hypochlorite of soda and the irrigations should be made at regular two hour intervals, either by means of a fixed irrigation apparatus or by a small hand syringe. The tubes should be of the diameter of the finger and are firmly fastened in place by means of a deep suture transfixing the tubes and the cervix itself.

Intubation by this method not only accomplishes he direct application of a powerful antiseptic rectly to the primary infective focus, but it prodes all the mechanical principles of proper drainge. Experience with a series of cases leads us to he conclusion that here is a valuable method of andling a condition for which no other means of eatment has proved satisfactory. Prompt inauuration of the treatment is of prime importance, as fter the fifth day postpartum, efficiency decreases t the rate of thirty-five per cent. a day. Late eatment in this manner is worthless.

The primary infection may remain localized in any f the areas noted above, or it may spread in many irections. This scattering of the infection takes ace in one of three ways: 1. By the endometrium, iving rise successively in its progress to salpinitis, ovaritis, pelvic abscess, and peritonitis. 2. By he lymphatics, directly through the wall of the terus, giving rise to pelvic cellulitis and septicemia. . By the blood stream, commencing at the placental te and spreading through the blood sinuses, giving se to thrombophlebitis, pyemia and septicemia.

In considering the lesions due to spread of the nfective process one significant fact presents itself. Of all the microorganisms the gonococcus is the nly one that appears to follow mucous membrane ssue. However, the gonococcus is not a particularly ommon factor in the development of puerperal nfection; hence it follows that pus tubes are by no means common sequelæ.

SALPINGITIS.

This is due primarily to extension along the tube rom the infected uterus. It is quite possible, however, that it may be the lighting up of an old process, resumably gonococcic. Abdominal pain is the preominating symptom in these cases and the involvement usually extends to the ovary and quite often o the peritoneum. Determination of the proper line f treatment for this class of cases calls for great icety of judgment. Pyosalpinx caused by an old onococcic infection is operated upon to best advanage after an extensive interval of rest, for the abdomen not only will have built up for itself a high degree of immunity, but a very effective diminution f the virility of this particular, microorganism has by this time been accomplished. It is safe to wait, if the patient is where she can be under observation.

On the other hand, when a pus tube, believed to be of puerperal origin, has been diagnosed to a reaonable certainty, its removal is indicated, for as ong as it remains, there is present a certain amount f danger to the patient from a further involvement f the peritoneum, due to leakage or rupture, or rom a metastatic complication. If not operated pon, there will be persistent fever and pain, with tle likelihood of any tendency to resolution.

OVARITIS.

There are two ways in which ovaritis may develop: By extension of infection from a tube, the ovary nd tube usually being found involved in a common ass. 2. By extension of infection directly from he uterus by means of the lymphatic channels, specially along the course of the ovarian ligament. his condition may become quiescent or may deelop into any one of the following conditions:

OVARIAN ABSCESS.

Postpartum ovarian abscesses of considerable size have been reported. The majority are small. The symptoms which they precipitate are similar to those of pyosalpinx and the treatment consists in removal. The leading factor in establishing the diagnosis will prove to be the history. Depending upon the mode of development, as indicated above, the operative findings will prove to be one of two classes: 1. A salpingoovaritis, with pus tube and purulent ovary bound together with a mass of adhesions which usually involve still others of the adjacent viscera. 2. An isolated abscess of the ovary with both tubes entirely normal, thus proving the course of the infection to have been by the lymphatic route.

PELVIC ABSCESS.

Pelvic abscess is usually the result of a leaking tube. In this condition there is frequently a combination of salpingitis, ovaritis and peritonitis, and if streptococcic in origin, the result may be most serious. Treatment by posterior colpotomy is indicated, as a transperitoneal operation, through dissemination of the peritoneal infection, is likely to prove fatal.

PELVIC CELLULITIS.

This is a lymphangitis of the connective tissue about the uterus, due to the streptococcus, staphylococcus or colon bacillus. The treatment consists in watchful waiting. The result will be—resolution or the development of a broad ligament abscess.

BROAD LIGAMENT ABSCESS.

Abscesses of the broad ligament may occur as the result of pelvic cellulitis or of the breaking down of septic thrombi. In this condition fluctuation will appear in about two weeks after the initial infection. There can be no question of the advisability of opening a parametric abscess as soon as pus is suspected. Sometimes after such treatment only a few drops of seropurulent fluid will be obtained, but this will be sufficient to clear up the condition. There is grave danger, however, in approaching a broad ligament abscess by the intraabdominal route, for the disturbance of a streptococcic infection is likely to result in fatal peritonitis.

It is possible to drain an abscess of this type from below. The dangers in this operation are: 1. Those arising from an inaccurate diagnosis of the exact location of the inflammatory process. 2. Those arising from the peculiar anatomy of the structures. The rectum, bladder, uterus, uterine vessels and the ureters may be irreparably damaged by an illadvised procedure in this region.

Broad ligament abscesses are demonstrably best treated by extraperitoneal drainage. In this operation, the principles of which were first suggested by Roberts, approach is made to the affected broad ligament by a small incision just over the internal abdominal ring. The aponeurosis of the external oblique is split, the round ligament demonstrated and followed into the space between the layers of the broad ligament. Upon the appearance of pus drainage is installed. This operation may be performed in connection with a median exploratory incision. A small series of cases has demonstrated the excellence of the results obtainable from this maneuvre.

SEPTIC THROMBOSIS.

The infection of thrombi filling the uterine sinuses after labor results in septic thrombosis. If the process remains limited to accessible veins, it may be possible to block its further progress by means of ligation. Sufficient data are not available upon this point.

PERITONITIS.

This condition is serious always and the treatment of the puerperal variety does not differ from the routine treatment of that due to any other cause. Rest, posture, and encouragement of elimination, together with drainage of exudate should localization occur, are the main factors. The final result, if fatal, is usually due to autointoxication caused by intestinal stasis.

SEPTICEMIA AND PYEMIA.

These conditions are manifestations of those infections disseminated by the blood stream. They are obviously most serious but are by no means universally fatal. The treatment is more of a medicinal than a surgical nature, aiming at raising the resistance of the patient. Serum or vaccine therapy has been reported as of value. Blood transfusion is generally advocated. Transfusion, with the utilization of an immunized donor, is theoretically of still greater value. Personal experience with direct transfusions, repeatedly performed, have been rather unsatisfactory. It must be admitted, however, that these measures were in every case carried out at a late stage of the infective process, when the condition was considered practically hopeless. It is quite possible that more prompt utilization of this measure might produce happier results.

Infections by the lymphatic route give rise to cellulitis and septicemia. The lymphatic type of septicemia is the most serious of all the end results of puerperal infection, as it is likely to be so virulent that it will become disseminated widely, even progressing to a fatal conclusion before any local lesions are evident.

The pathology, symptoms, sequelæ, and treatment of puerperal infection is substantially as has been indicated, whether the situation develops subsequent to a full term delivery, or to an abortion. Early discovery and courageous institution of proper measures of treatment will do much to conquer the most dreaded complication of obstetrical practice.

47 West Ninety-fourth Street.

Chemical Changes in the Toxemia of Pregnancy

By MAX KAHN, M.A., M.D., Ph.D.,

New York,

Chief of Diseases of Metabolism, Beth Israel Hospital, and Associate in Biochemistry, Columbia University.

It was Zweifel who called eclampsia "the disease of theories," and looking through the literature on the subject one is impressed with the aptness of this designation. As in other branches of medicine, where too many theories flourish, little is known of facts that actually prevail, and many are tempted to cover with luxuriant verbiage the vast desert of ignorance and speculation.

The causes of toxemia of pregnancy may be classified under the following six headings:

1. Disturbances in fetal metabolism.
2. The entrance of fetal or placental elements into the maternal circulation.
3. Poisoning by substances formed or retained in the placenta.
4. Disturbances of maternal metabolism.
5. Anaphylactic reaction.
6. Mammary toxemia.

Professor Williams, reviewing all these etiological factors, concludes, as everyone must who is cognizant of the subject, that "it is evident that its cause is still undiscovered. All that we know positively is that the disease is accompanied by characteristic lesions in the liver and by striking changes in metabolism."

I shall endeavor to record here the typical chemical changes in toxemia of pregnancy and eclampsia, and, at the risk of burdening the literature with another theory, propound what, in my opinion, is the basic factor in the etiology of these conditions.

The pathological changes or pathochemical disturbances that are present in the toxemia of pregnancy have their initial appearance in the liver structure In all pregnant women there is general abdomina congestion with occasional dysfunction of liver resulting in symptoms, mild at first, and later becoming quite distressing. The Germans have noticed these disturbances in the liver in normal gestation, and they call this liver *Schwangerschaftsleber,* or the liver of pregnancy. These alterations are first a mild congestion with mild degrees of fatty infiltration This may gradually pass to acute yellow atrophy o the liver or to the pathological changes noticed by Ewing in eclampsia.

One becomes convinced more and more that the disturbance in one of the functions of the liver i the fundamental factor in the causation of the toxemia of pregnancy. It must be remembered that o the various functions of the liver its detoxicating influence is one of the most important, and one also to which much attention has been devoted. It is quite well known that toxic radicals liberated during th process of normal or abnormal intestinal digestion are carried to the liver by means of the portal circulation, and there either neutralized or oxidized o conjugated to lessen or remove the toxic influenc of the substance. One of these methods of detoxication is the union of aromatic radicals with sulphuric acid and their excretion in the form of conjugated sulphates (ethereal sulphates) in the urine

Since Städeler found phenol in cows' and horses urine, Landolt, Lieben, Hoppe-Seyler, Buliginsky and Munk found traces of it in normal human urine and Salkowski observed that in ileus and other ob ructive intestinal disease the excretion of phenol the urine was much increased.

This formation of phenol and phenolic substances, resol, indol, skatol, etc., has been ascribed to the ction of intestinal bacterial flora. Such organisms s the Bacillus coli communis, which is a normal inabitant of the intestinal canal, are harmless under rdinary circumstances. In conditions of injury to e intestinal mucosa these organisms become viruent (Fermi and Salto). Other organisms, such as e Bacillus putrificus, the Bacillus aërogenes capulatus, which are obligatory anaërobes, thrive in e colon when there is no oxygen (Herter) and reak up protein into the carbocyclic toxic subtances.

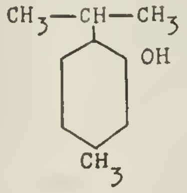
It has been demonstrated by Baumann that these plit products are very toxic, but that when they re united with sulphuric acid they have lost their oisonous effect. Baumann found that phenol sulhate was a normal urinary constituent and that the dministration of phenol increased the elimination f phenol sulphate in the urine. Duncan and Herter eported that not only phenol, but also other subances, were excreted in the urine as conjugated ulphates.

In normal conditions of the alimentary tract trauss and Philipsohn found no phenol in the urine f human beings, and they concluded that under ormal conditions the phenol and other radicals ere conjugated with sulphuric acid. According to ese authors, the liver is the seat of this conjugaon. In hepatic disease there have been observed isturbances in the elimination of the ethereal sulhates. In conditions of jaundice Biernacki found our times as much ethereal sulphates as normally. arenberg and Perroy found an increased excretion f indol and skatol in the urine of jaundiced indiiduals. Labbé and Vitry obtained similar results. agrageas obtained varying amounts of ethereal ulphates in icteric patients.

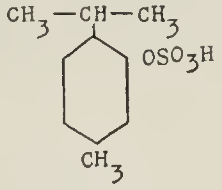
The question has been discussed by Eiger and lopazde whether the aromatic compounds formed the system are diminished in amount and detroyed under normal conditions of hepatic activity, nd whether in cases of disturbances of the function f the liver these compounds are obviously increased nd placed at the disposal of the liver for conjugaon with sulphuric acid. The subject is important its relation to cases of diseases of the hepatic arenchyma, more so than in cases of simple biliary tasis. The ethereal sulphuric acids are most freuently, both absolutely and relatively, increased in trophic cirrhosis of the liver, and most markedly tumors of the liver.

In order to study the detoxicating function of e liver, the following method has been devised. t has seemed to me advisable to administer a definite uantity of an aryl compound and to examine the rine for the conjugated products of this substance. or the purposes of this work thymol seems to be e most suitable aromatic substance to use.

Thymol is metaisopropylcresol. Baumann and erter have found that thymol sulphuric acid occurs the urine of rabbits after thymol administration. ogelius reported that the feeding of 0.5 gram thyol increases the output of ethereal sulphates from .05 gram to 0.107 gram to 100 c. c. of urine. Blum, Preusse, and Finizio have separately reported that thymol is eliminated in the urine as thymol sulphuric acid and as thymol hydroquinone sulphuric acid.



Thymol



Thymol sulphuric acid

I adopted the following technic for the determination of hepatic insufficiency by means of the ethereal sulphate output.

The patient received a dose of castor oil to clean out his bowels. He was then kept on a known diet for two days, during which time the urine was collected, preserved with a few drops of formaldehyde, and analyzed for total sulphur and ethereal sulphates.[1] On the third day the patient received a capsule containing 0.5 gram thymol. A dose of olive oil was administered to the patient several hours after the thymol dose in order to dissolve the thymol and increase its absorption from the intestinal canal. The urine was collected for the next forty-eight hours, preserved with a little formaldehyde and analyzed for total sulphur and the ethereal sulphates.

If all the thymol were absorbed and if all the thymol were conjugated with sulphuric acid and none with glycuronic acid the 0.5 gram thymol would be excreted as 0.7666 gram thymol sulphuric acid. This would cause a marked increase in the percentage of the ethereal sulphates. If the liver were not functionating properly, the thymol would not be conjugated and the percentage of ethereal sulphates would be only slightly different from what it had been on the first two days.

It is possible that each individual cell of the hepatic parenchyma takes part in all of the liver functions; it is probable, however, that different portions of the liver lobule may have specific functions. In the former case it is most likely that reduction in the ability of the liver to perform one function will be accompanied by a proportional reduction in all the liver functions; in the latter case one or more functions of the liver may be disturbed without affecting the other hepatic functions. One objection to the study of the function of any organ as an index of disease of that organ is that it is perhaps possible for the healthy portion of the diseased organ to compensate and assume the work of the whole gland. In such a condition, of course, the functional capacity of the organ may be normal and would be no index of the pathological changes in that organ. Under these circumstances only marked destructive changes would leave their impress on the functional sufficiency of the organ. We have found, however, that by these means it is possible to study the liver function in disease and in pregnancy.

In the beginning of pregnancy there is a disturbance in the detoxicating function of the liver. As normal pregnancy continues, the functional capacity of the liver returns to normal. Should the hepatic structure not be able to return to a state of equilibrium in function the toxic radicals will pass through its structure injuring it more and more, will enter the general circulation, and will affect the other organs of the body, especially the kidneys, so that ultimately a marked pathological disturbance is induced which may result in death due either to intoxication of the primary cause or to the disturbed pathology set up, as, for example, nephritis.

---

[1] The total sulphur was analyzed by Benedict's method, and the ethereal sulphates by Folin's method.

INFLUENCE OF DIET ON TOXEMIA OF PREGNANCY.

That the diet has a marked influence in the occurrence of the toxemia of pregnancy is a well known fact. In the great war, when diet played a great rôle in all the functions of life, special studies were made on the influence of diet as an etiological factor in eclampsia. I shall quote Kosmak's excellent summation of this subject:

"Warnekros and other German writers noted reductions in the number of cases of eclampsia in various clinics during this period. Mayer attributed the change to the reduction in the frequency of sexual contact, for he considers the repeated introduction of spermatozoa in the female organisms as a factor in producing anaphylactic processes. But this theory is regarded as farfetched by his German colleagues, who attribute the lessened occurrence of eclampsia to the lowered protein and fat contents of the war diet, which brought about a reduction in the functional hyperactivity of the liver and kidneys so often found in the second half of pregnancy.

"These observations on war diet reduction seem to be in agreement with those made by others in peace times, for it has often been stated that eclampsia is more frequent in northern than in southern countries and that strong, full blooded women are more frequently affected than those who are thin and less well nourished. The geographical differences are attributed to variations in the diet, a greater amount of fat being taken in the northern and more vegetables in the southern latitudes. A French observer, Lafont, has noted that in Algiers the wives of the natives are much less frequently afflicted with eclampsia than the wives of immigrants, which he explains by the fact that the natives eat more vegetables and the immigrants more salty foods. In Turkey eclampsia is stated to occur rarely and in one of the largest lying-in hospitals of Constantinople an average of only two cases has been observed. It has also frequently been affirmed that eclampsia is more frequent during the winter than the summer months, which may be assumed to be due to the influence of the food, as more fat is taken in the colder season than during the warmer period.

"It is to be expected that the clinical picture usually recognized as pregnancy nephritis, which is frequently a forerunner of eclampsia itself, can be favorably influenced through changes in food stuffs. For instance, Warnekros's report from Bumm's clinic in Berlin, shows that the incidence of nephritis during the two war years of 1915 and 1916, was about one per cent. of the total number of labors, while during the four previous years it had varied from two to four per cent. These figures were confirmed by an examination of the statistics of three other obstetrical hospitals in Berlin. The number of eclamptic cases showed a similar diminution, being one per cent. or less, in each case, as compared with from two to four per cent. during the years before the war. Warnekros thinks that these observations indicate that there is marked relation between eclampsia and diet, and, therefore, point the way to the prophylactic treatment of the disorder."

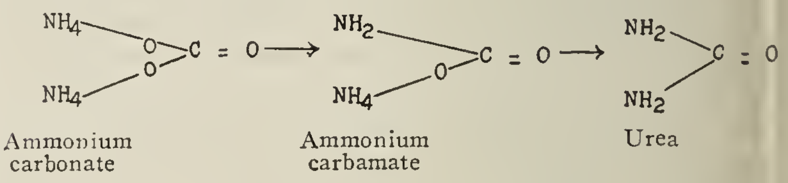
It is possible, I think, by proper study and by proper metabolic management, to prevent the onset of toxemia of pregnancy in women who are anxious to have children and who give a history of former dreadful experiences with convulsions of the mother and death of the fetus.

The metabolic disturbances that are present are secondary, in my opinion, to this dysfunction of the liver and are only easily understood if this hepatic disturbance is constantly remembered.

EFFECT ON THE AMMONIA COEFFICIENT.

It is one of the normal functions of the liver to produce urea from the byproducts of the breakdown of the body. It does this in the following way:

The ammonia which is brought to the liver in union with carbon dioxide and water is dehydrated by the liver to form urea, thus



Normally this urea forms about eighty per cent of the total nitrogen in the urine. Normally, also the liver permits only a little of the ammonia to escape unchanged into the urine. This little i about three to five per cent. of the total nitrogen in the urine. The ratio of ammonia nitrogen to tota nitrogen in the urine is the socalled ammonia coefficient.

When the liver is not functioning properly it permits much more ammonia to escape unchanged into the urine and thus increases the ammonia coefficien to very high figures, with the corresponding diminution in the urea output.

J. Whitridge Williams, in 1907, directed particular attention to the ammonia coefficient—the amoun of ammonia nitrogen compared with the amount o total nitrogen in the urine. He not only believe that the relative increase in ammonia was in direc ratio to the severity of the toxemia, but that in thi way it would be possible to estimate accurately th value of the treatment instituted to relieve the condition and also to decide how far a patient might b allowed to go before interference with pregnanc was justified. In the enthusiasm of having at las found a practical method to deal with a difficul decision, he established the rule that an increasin ammonia nitrogen of ten per cent. or more of th total nitrogen justifies interference with pregnanc Wider experience soon established a more conservative policy which Williams was among the first t adopt, but the fact remains that the ammonia coefficient is still one of the potent factors in determining just what Williams originally asserted—an inde to the severity of the toxemia as well as an inde to the point beyond which it is not safe to allow th pregnancy to go.

BLOOD CHEMISTRY.

Due to the secondary influence of the toxin ci culation on the kidneys, a condition of nephritis i induced with the retention of the various nonprotein nitrogenous compounds in the blood, such as urea, creatinin and uric acid. These substances in themselves are not the toxic factors responsible for the toxemia, but are only an index of other substances which are toxic and which overwhelm the patient.

The urea nitrogen, which normally is about sixteen mgs. to 100 c. c., is increased to fifty or over; the nonprotein nitrogen which normally is about twenty-five mgs. to 100 c. c. is increased to eighty or more. The creatinin and uric acid in the blood which are good prognosticators may be increased to four and six mgs., respectively.

ACIDOSIS.

With the nausea, the vomiting, the retention of acid substances, etc., there is a diminution of the alkali reserve with the resultant acidosis. This is not the cause of toxemia of pregnancy, but is a result of it. This acidosis is measured by the CO_2 combining power of the blood (by the Van Slyke method) and by the hydrogen ion concentration of the blood.

In the severe vomiting of pregnancy, a condition similar to starvation is set up with the resultant dysbolism of the fat into betaoxybutyric acid, diacetic acid and acetone. These substances need not be present, however, for a condition of true acidosis to exist.

CALCIUM CHANGES.

There is always a distinct disturbance in the calcium metabolism of the pregnant woman. In fact, Drennan thought that this was the cause of toxemia of pregnancy. The formation of the bony structure by the fetus causes a large mobilization of the lime salts by the mother with resultant disturbances in the calcium content of the blood. There seems to be a distinct relationship between the calcium metabolism and carbohydrate metabolism, and it is possible that this mobilization of calcium plays a rôle in the lactose output by the lactating mother.

Ingestion Glycosuria an Aid to Early Diagnosis of Pregnancy*

Preliminary Report

By CHARLES-FRANCIS LONG, B.A., M.D.,
and JOHN COOKE HIRST, 2nd, B.A., M.D.,
Philadelphia.

It is a curious fact that the first work on a test peculiarly of interest to the obstetrician should have been done in a clinic that at the time was dealing with a series of neurological cases. In 1895 Dr. R. von Jaksch (1), while studying glycosuria following ingestion of 100 grams of glucose, found it usually absent in chorea and syringomyelia, but when two cases of this sort in pregnant women reacted positively his assistant, Dr. Frederick Lanz, decided to investigate the phenomenon. Lanz (2) reported a series of thirty cases, all but two of which had reached the eighth month of pregnancy. From his work he concluded that the "assimilation threshold" for glucose is lowered in pregnancy and rapidly returns to normal after labor. Hofbauer (3), in 1899, using practically the same technic, reported forty-five cases, thirty-nine positive and six negative. His conclusions were that glycosuria is a symptom of pregnancy which disappears when the physiological relationship between the fetus and maternal parts is destroyed.

The fact that glycosuria may be seen in pregnancy as a transient symptom has been noted by various writers since 1856 when Blot (4) first brought it to the attention of the profession. In the recent literature Guggisberg (5), Cron (6), Bauer (7), Motzfeldt (8), and Wallis and Bose (9) have all reported studies on the spontaneous glycosuria of pregnancy, and their conclusions may be stated as follows: 1. The spontaneous glycosuria usually appears after the sixth month of pregnancy. 2. It is mild in type, the amount in the urine being usually less than one per cent., it is often intermittent, and there is slight, if any, hyperglycemia. 3. The sugar excretion is independent of the carbohydrate in the diet. 4. There are no other symptoms of diabetes. 5. The glycosuria disappears after labor.

The relative frequency of spontaneous glycosuria in pregnant women is given in Table I.

TABLE I.

THE INCIDENCE OF SPONTANEOUS GLYCOSURIA IN PREGNANCY.

1. Bauer,	0.75 per cent.	6. Reichenstein,	12 per cent.
2. Cron,	4 per cent.	7. Stolper,	18 per cent.
3. Williams, J. W.,	5.6 per cent.	8. Ludwig,	22 per cent.
4. Hirschfeld,	10 per cent.	9. Lepine,	40 per cent.
5. Van Noorden,	10 per cent.	10. Brocard,	50 per cent.

On reviewing the records of the Maternity Dispensary at the Hospital of the University of Pennsylvania from July 1, 1921, to January 1, 1923, in 547 pregnancy case records only four could be found in which sugar in the urine was reported. One of these was definitely diabetic and the glycosuria was therefore not attributable to pregnancy. Consequently, as far as these records go, we may say that glycosuria occurred in 0.55 per cent. of this series of cases. The high figures obtained by certain investigators are doubtless due to the inclusion of cases of lactosuria in their series. In Cron's series of 2,200 cases lactosuria occurred in 3.5 per cent. of the pregnancies.

The recognition of glycosuria as a system of early pregnancy is the clinical outcome of work done by Ryser (10) in 1916 and Gruenthal (11) in 1919. The former determined that when pregnant women were fed on a series of different sugars, the blood sugar values never exceeded normal physiological limits. The latter showed that the blood sugar curves were identical in nonpregnant and pregnant women after ingestion of like amounts of glucose, but that the pregnant women responded with glycosuria. The blood sugar values never exceeded 200 mg. to the 100 c. c. of blood. In 1920 Frank and Nothmann (12), of Breslau, published a series of cases in which they had used ingestion glycosuria as the sign of early pregnancy and had tested nineteen women without one failure. Having a preliminary specimen of blood and urine, they administered 100 grams of glucose on a fasting stomach, then collected urine specimens every fifteen minutes, and blood every hour for two hours. Considering 190 mg. to the 100 c. c. of blood as top normal for the blood sugar value, they found that the blood sugar never exceeded this figure and that the glycosuria had always appeared within one hour in positive cases. They found the test to be unreliable after the third month. A positive result was obtained from an early ectopic gestation when fetal and maternal parts were still in living relationship.

---

*From the Out Patient and Ward Services of the Department of Obstetrics and the William Pepper Laboratory of Clinical Medicine, Hospital of the University of Pennsylvania.

Presented before the Annual Meeting of the Undergraduate Medical Association of the University of Pennsylvania, April 19, 1923.

Table II shows the results of other investigators in using this method. It will be noted that of 259 cases, 247 reacted positively and 12 negatively.

TABLE II.

RESULTS IN WOMEN PREGNANT ONE TO THREE MONTHS, INCLUSIVE, USING THE FRANK AND NOTHMANN TECHNIC.

Series	Positive	Negative	Negative Controls
1. Frank and Nothmann (12)	19 6 (COH meal)	0	7 4
2. Kamnitzer and Joseph (20)	16 (COH meal)	0	30
3. Nürnberger (18)	18	0	—
4. Seitz u. Jess (17)	5	5	—
5. Schilling u. Göbel (21)...	5	0	—
6. Lembcke u. Lindig (16).	16	0	—
7. Dietrich (15)	7	4	—

9. Welz and Van Nest (22)	15	3	9
10. Williams, Philip (19)....	20	0	All except one.
	247	12	

In the technic used at the Hospital of the University of Pennsylvania, several changes were made from the original Frank and Nothmann technic, as follows:

1. The patient took no breakfast and voided a preliminary specimen of urine which was tested for a reducing sugar by the Fehling test.
2. One hundred grams of Franklin granulated table sugar were given dissolved in two glasses of hot water.
3. One hour later a specimen by catheter was obtained and blood drawn from the arm, which was sent to the Pepper Clinical Laboratory where a Folin and Wu blood sugar determination was run on it. The urine was examined by the Fehling and Benedict's qualitative tests. No quantitative tests were done, for it was a foregone conclusion that the appearance of enough sugar to reduce the copper solutions would be abnormal. On two of the early positives, fermentation tests were set up to establish that a fermenting sugar was really being voided. Since these were positive, and the preliminary specimen negative to Fehling's, we felt justified in concluding that the positive reaction after the ingestion of sugar was due to glucose.

The Franklin sugar used in the test is one hundred per cent. cane sugar, breaking down to fifty per cent. dextrose and fifty per cent. levulose (27). The use of table sugar instead of glucose is a practical point that commends itself as eliminating a prohibitive factor in the original German technic, for cane sugar is everywhere available. The further simplification in taking one urine and blood specimen at the end of an hour makes toward less discomfort for the patient and is well beyond the time of the first appearance of glycosuria in positive cases (12 and 19). Folin and Borglund (13), in 1922, showed by a series of experiments that two hundred grams of pure glucose could be given a normal individual without consequent glycosuria and that a like amount of pure levulose could be given with the same result. In all our later cases, 125 grams of table sugar were used to make up for possible loss in the intestinal tract.

TABLE III.

AUTHORS' SERIES OF CASES AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, USING FRANKLIN TABLE SUGAR.

Case	Last Seen Period	Result	Blood Sugar	Remarks
1.	9 months	positive	100 mg.	pregnant
2.	7 weeks	positive	126 mg.	pregnant
3.	2½ months	negative	136 mg.	pseudocyesis not pregnant
4.	————	negative	156 mg.	visceroptosis
5.	7 months	negative	115 mg.	pseudocyesis—no uterine enlargment
6.	10 months	positive	125 mg.	pregnant
7.	full—8 weeks scant—3½ weeks	negative	238 mg.	ruptured ectopic
8.	8 months	positive	117 mg.	pregnant
9.	11 weeks	positive	152 mg.	pregnant
10.	full-11 weeks scant-4½ weeks	positive	146 mg.	pregnant — unruptured left ectopic
11.	9 months	negative	115 mg.	pregnant
12.	5 months	positive	100 mg.	pregnant
13.	11½ weeks	positive	79 mg.	pregnant
14.	9 months	negative	165 mg.	pregnant
15.	8 months	negative	156 mg.	pregnant
16.	4 months	positive	100 mg.	pregnant—abortion one month later
17.	————	negative	———	two days after operation for incomplete abortion
18.	14½ weeks	negative	146 mg.	aborted six days later
19.	10½ weeks	positive	162 mg.	pregnant
20.	9 weeks	negative	167 mg.	pregnant
21.	————	negative	132 mg.	right hydrosalpinx
22.	10 weeks	positive	190 mg.	pregnant—child born four months before; fermentation test—positive
23.	11 days	positive	90 mg.	patient menstruating during pregnancy

Case	Last Seen Period	Result	Blood Sugar	Remarks
24.	11 weeks	positive	133 mg.	pregnant
25.	8 weeks	positive	146 mg.	pregnant
26.	9 weeks	positive	———	pregnant. Hymen intact
27.	———	positive	167 mg.	pregnant — no period since last delivery
28.	———	positive	112 mg.	pregnant — no period since last delivery
29.	7 weeks	positive	157 mg.	unruptured ectopic gestation
30.	13 weeks	negative	131 mg.	bleeding six weeks; incomplete abortion
31.	———	negative	160 mg.	nonpregnant
32.	3½ months	negative	168 mg.	bleeding two weeks; incomplete abortion
33.	———	negative	138 mg.	menstruating
34.	11 weeks	negative	103 mg.	brownish discharge for two weeks followed by miscarriage
35.	6 weeks	negative	130 mg.	nonpregnant
36.	———	negative	130 mg.	menstruating
37.	———	negative	107 mg.	nonpregnant
38.	———	positive	———	fibroids and salpingitis fermentation test negative
39.	4 months	negative	133 mg.	nonpregnant

Considering first the levels of the blood sugar, a quick glance will show that no case showing glycosuria exceeded 190 mg. to 100 c. c. of blood. This, according to Ryser and Gruenthal, is the upper limit for average ingestion hyperglycemia. The consensus of opinion in the literature seems to be that a blood sugar value over 200 mg. to 100 c. c. of blood shows a definite fault in the carbohydrate metabolism.

In order to attain some semblance of uniformity in work done on the dispensary class of patients, pregnancy on our charts is dated from the last seen period. On this basis we have fourteen positive results, and one negative result up to the end of the fourth month, and four positives and three negatives after the fourth month, all in confirmed pregnancies. The earliest recorded positive is seven weeks from the last seen period. We have three times been able to diagnose unruptured ectopic gestations, confirmed at operation, for maternal and fetal parts were still in living relationship, consequently the tests were positive. The effect of the break in this relationship is shown in cases 7, 18, and 34.

Although we have no positive result in the absence of pregnancy, there have been five reported in the literature (15); Lembcke and Lindig, ovarian cyst (16); Seitz and Jess, ovarian cyst (17), pyosalpinx, and double parovarian cyst; Nürnberger, hysteria, Fröhlich's syndrome (18).

Case 22 presented an interesting question. What value may we place on a positive test in a woman who has seen no period since her last child and is still lactating? A series of five nonpregnant lactating mothers gave the results shown in Table IV.

TABLE IV.

RESULTS IN LACTATING MOTHERS AFTER INGESTION OF 100 GRAMS OF FRANKLIN TABLE SUGAR.

Case	Urine Before	Urine After	Blood Sugar	Remarks
1.	negative	negative	158 mg.	child one week old
2.	negative	negative	78 mg.	child five days old
3.	negative	negative	153 mg.	child nine days old fibroid uterus
4.	negative	negative	87 mg.	child three days old
5.	positive fermentation negative	positive fermentation negative	114 mg.	child six days old

All the tests were negative except in the last case and here neither urine fermented, showing that no glucose was present and the extruded sugar was probably lactose. From this series we may conclude that lactation offers no bar to the use of this test and the result may be trusted even in the presence of lactosuria if the urine is fermented with yeast. This is further exemplified by case 38. The patient had been diagnosed pregnant by fifteen practitioners and specialists, her breasts were secreting, and the gynecological findings were confusing. The sugar found in running the test did not ferment, and she was therefore diagnosed not pregnant. At operation multiple fibroids and salpingitis were found, with a nonpregnant uterus. To obviate the objection raised against the Abderhalden test, we also ran a series of four normal men according to the ingestion technic and all were negative; the blood sugar values ranged from 102 to 190 mg. to 100 c. c. of blood.

Working on the hypothesis that the ingestion glycosuria of pregnancy is a type of renal diabetes, Kamnitzer and Joseph (20) proposed to find that dose of phloridzin which would not produce renal diabetes in the normal, but would produce it in the pregnant woman. Their technic as first published called for a dose of 2.5 mg. of phloridzin.

TABLE V.

RESULTS OF VARIOUS INVESTIGATORS WITH BOTH PHLORIDZIN TECHNICS.

Series	Positive	Negative	Controls Positive	Not Pregnant Negative
FIRST TECHNIC:				
1. Kamnitzer u. Joseph (20)	29	0	7	63 10 men
2. Schilling u. Göbel (21)	9	0	7 febrile	70
3. Hollingsworth (23)	17	2	6 2 men	22 5 men
4. Williams (19)	0	15	—	—
SECOND TECHNIC:				
1. Kamnitzer u. Joseph (24)	62	0	6	207
2. Zondeck (25)	—	—	15 per cent. of controls.	
3. Leskinen	13	0	5	26

In 1922 (24) Kamnitzer and Joseph published a revised technic which was adopted in our series—a preliminary specimen of urine is voided and the patient given two mg. of phloridzin intragluteally. At the same time two tumblerfuls of water are given. The urine is collected at the end of a half hour and tested for sugar by the Fehling and Benedict qualitative methods. Our results have been thoroughly disappointing. In a series of eleven cases we have had but one positive result, occurring in a nonpregnant woman with a myomatous uterus, and explained by a slip in technic, for she had a meal fifteen minutes before the phloridzin was administered. The series included six pregnancies before the fourth month, three nonpelvic affections, and two patients the day after they had been operated upon for incomplete abortions. The cause of the ingestion glycosuria is not known and from so small a series nothing constructive can be deduced.

SUMMARY.

1. Our series brings added evidence to strengthen the assumption that an ingestion glycosuria can be induced in the early months of pregnancy, that it is a valuable diagnostic aid, and that the glycosuria disappears when the fetal and maternal parts are no longer in physiological relationship. The literature shows a ninety-five per cent. accuracy with the glucose ingestion diagnostic technic in the first three months of pregnancy.

2. The use of table sugar instead of glucose and qualitative instead of quantitative tests for sugar in the urine does not affect the results, but makes the test more practicable. It is necessary to determine blood sugar only in positive cases to eliminate values over 200 mg. to 100 c. c. of blood.

3. Lactation seems to have no effect on the appearance of glucose in the urine during the test.

4. The phloridzin technic has yielded no satisfactory results.

Further study will be directed along the following lines:

1. Continuation of the sugar and phloridzin series.
2. A series of menstruating women to determine the effect of this act on the test (26).
3. A series of women at the menopause, surgical or natural, when disturbing variations of menstruation so often occur.
4. A series of women with socalled ovarian dysfunction with special reference to scanty menses, increased weight, and obvious endocrine disorder.

The authors' references will appear in their reprints.

Views and Observations on Abortions

By L. DROSIN, M.D.,
New York,
Visiting Obstetrician and Associate Gynecologist, Beth David Hospital; Chief in Gynecology, Beth David Dispensary.

As the treatment of miscarriage and premature labor is essentially the same as that of full term delivery, it is not my intention to deal with either of these conditions in this paper, notwithstanding the fact that in some of the cases to be reported pregnancy had advanced as far as the fourth month. Some of the clinical pictures I am setting forth are not of the everyday variety, and are encountered more often in private practice than in hospital work. I shall emphasize only those facts which textbooks touch upon lightly, indifferently, or not at all.

CAUSES OF ABORTION.

Maternal.—In many cases we are able to find no more definite cause than obstipation, or the fact that the patient lives on the top floor, necessitating much stair climbing, or a combination of two such factors. If the uterus in its nonpregnant state is anteflexed, or normally anteverted, this position will be exaggerated during the early part of gestation, or if a normally anteverted uterus is antecessed—in contradistinction to retrocessed—or descended, this position will also tend to be made more positive at the outset of pregnancy. I have often seen such an exaggeration when but a few days had elapsed after the time of the first missed period. Unless this flexion is overcome by the softening which results from the attachment of the ovum near the internal os—particularly if the attachment is to the anterior wall—or to general softening of the uterus, or the uterine supports early become infiltrated and softened, thus permitting the uterus to ascend or recede, as the uterus enlarges the fundus will approximate and often actually impinge upon the symphysis pubis. This brings about a continuous irritation of the uterus especially during active motion and this state of irritation is supplemented by the pressure of the relatively full bladder, which is unable to fill as completely as in the nonpregnant state. Added to these two agents of irritation we may find a third—constipation—which is usually present very early in pregnancy, and serves to exert a counterpressure upon the uterus, causing congestion or hyperemia. We know that a distended bladder after delivery will often cause hemorrhage, and in the same way a distended bladder as described above in the early months of pregnancy may be instrumental in causing abortion under the conditions just mentioned.

Under normal conditions, when pregnancy begins, the uterus will descend, and as a rule, antevert and dextrovert or flex, though occasionally this turning or flexion will be toward the left. With these lateral inclinations the uterus will not be irritated by impinging upon the symphysis, the full bladder will act only as would a firm hot water bag supporting it, and the impacted rectum will have a similar influence. Thus, the position of the uterus, the action of the distended bladder and rectum, and probably other causes of which we are ignorant, in addition to acting directly upon the uterus, undoubtedly have a reflex action upon the adnexa, and help, hinder, or delay the occurrence of certain results.

If the vagina is long and narrow, so that it maintains an ascensus or suprascensus—terms used in contradistinction to descensus and prolapse—of the uterus, preventing it from sinking into the pelvis, and cutting off an increase of the blood supply by exerting pressure on the cervix and lower part of the corpus thus producing local anemia of the uterus, the embryo will die from insufficient nutrition. Rigid ligaments, or a short vagina which fails to stretch, and so limits the blood supply and prevents the rising and growth of the uterus, will have a similar effect. The uterus may also be prevented from rising out of the pelvis and enlarging by the existence of fibrosis or hypertrophy, particularly when associated with adhesions, which will result in similar conditions of anemia and malnutrition.

Another cause of abortion is an infantile uterus which has developed sufficiently to permit conception but which is unable to enlarge in proportion to the growth of the embryo.

Fetal.—When conditions favor excessive motility of the fetus, the cord may become so twisted as to cut off the blood supply to the embryo. I have seen three cases of abortion where the cord was twisted as tightly as a fine screw thread and no other cause for the abortion was observable. In another case of ten weeks' gestation, the cord showed a black smooth surfaced area embracing its entire circumference and about three sixteenths of an inch long, which had no characteristic twisting. This was undoubtedly a case of apoplexy of the cord.

It is also certain that functional or organic factors inducing sterility may at times abate sufficiently to permit conception to take place, but will thereafter operate to produce expulsion of the ovum.

SYMPTOMS OF ABORTION.

Threatened abortion.—In addition to predisposing causes, with or without bleeding, and usually occurring between the tenth and twelfth weeks of gestation, I wish to include the following picture: A large uterus of unusually hard consistency, descensus, immovably fixed, anteflexed and apparently that part of the fundus which embraces the continuation of the structures of the tubes and round ligaments forming a hard crest or spine. This spine is the most anterior part of uterus and is located behind or impinges upon the symphysis. Unless the uterus can soften and rise out of the pelvis the patient will abort. In primiparæ the uterus may be moderately cystic instead of hard.

Inevitable abortion.—Here we have much more profuse bleeding than when the abortion is merely threatened, accompanied by more regular labor pains, complete disappearance of flexion at or above the internal os, a coneshaped corpus and cervix, and the cervix including the internal os more or less dilated. I have seen a large number of cases with bleeding as the only symptom and where it would seem as if the uterus—although unable to rise out of the pelvis—had made one supreme effort to do so, for it will be found to be supracessed, of an even, firm consistency, having lost its characteristic cystic feel, and likewise the vaginal walls will be supracessed and the vault of the vagina very tensely drawn up and widened out, forming a conical dome enclosing a hollow space, which disappears after abortion.

As all the patients whom I have seen in this condition aborted within two or three days, I feel justified in classing it as one of inevitable abortion. I have seen many patients—both pregnant and nonpregnant—in whom the palpating finger could make out a similar "dome shape," but always the cervix was in normal position, and the vaginal wall so soft and relaxed that it yielded to palpation. This indicates the part the vagina plays in abortion.

In any case where bleeding is the only symptom the appearance of the discharge upon the examining finger is of diagnostic significance. When it has the consistency and color of mud, or is of a dirty ashen shade, it is at least evidence of a threatened abortion and this is likewise true if it is mucosanguineous with a large proportion of mucus, of a dirty yellow color and a consistency suggestive of soft Limburger cheese. Such a fluid is usually composed of the alkaline constituents of blood, possibly shreds of amniotic membrane, discharged as a result of decidual endometritis, mucus from the cervical plug, and probably an admixture of seminal fluid, all acted upon by the acid vaginal secretions.

But if the examining finger brings away a thin, transparent albuminosanguineous fluid containing translucent particles, the edges of which merge with the containing medium, we have positive evidence that the embryo is dead, as it indicates that the amniotic membrane is undergoing decomposition. This latter phenomenon is due to the fact that the amniotic membrane is ordinarily the weakest attachment of the ovum, as well as the lowest and most insufficiently supplied with blood; moreover, it is the most attenuated because of the stretching effect of the weight of the liquor amnii and fetus.

In missed abortion of about two or three weeks' duration or longer, the uterus will as a rule change from a cystic to an edematous consistency. A typically edematous uterus with symptoms of threatened abortion, and more particularly when the consistency is known to have changed from cystic to an edematous condition, is diagnostic of the death of the ovum. On the other hand, missed abortion, taking place before physical signs of pregnancy have appeared, will give no uterine evidence of pregnancy until the patient actually aborts.

TREATMENT OF ABORTION.

If abortion is merely threatened, do not give ergot, even in very small doses, as such measures will usually not only fail to stop the bleeding but will tend to make abortion inevitable. This latter result, in my opinion, is brought about either by the temporary diminution in blood supply (nutrition) or by retaining the blood which would otherwise come away, and as this retained blood increases in amount and forms an enlarging clot, it will gradually separate the ovum; or by the contraction of bloodvessels and uterine wall, the secondary relaxation of the same will cause increased bleeding and increased separation of the ovum.

In inevitable spontaneous abortion, when bleeding is either slow and moderate, or profuse with sudden onset, with or without pain, one c. c. of aseptic ergot, hypodermically administered even without vaginal packing, will prevent hemorrhage, or reduce bleeding to a minimum by causing contraction or hardening of the uterus or by serving to bring on strong pains, and with such conditions present we have little danger of hemorrhage. In general it will hasten and facilitate the process of emptying the uterus. If there are no pains they will be brought on within twenty-four hours, and in my experience the dose has not required repetition. Should the indications warrant it, however, the dose may be repeated any time within the twenty-four hours. As a further precaution against hemorrhage, watch for distended bladder and impacted rectum.

Although the uterine content may apparently be completely expelled, in the large majority of cases (proved by curettage) enough decidua and placental tissue may remain to delay involution, cause chronic subinvolution, or retard the closing of the cervix. Putrefaction and subsequent infection are thus invited, and even if these do not take place, we may have bleeding or spotting for an indefinite period, sufficient to reduce greatly the patient's general vitality. The condition of the tubes and ovaries must also be considered. While I do not advocate curettage indiscriminately, by doing so under strictly aseptic precautions immediately, or within twenty-four hours if bleeding is not profuse, all these sequelæ may be obviated. Proper aseptic conditions can usually be obtained almost anywhere if sufficient caution and intelligence are exercised. If the patient is not in a hospital all the instruments should be left in the sterilizer, pouring off only enough water to keep them at least partially submerged and adding lysol to the water, and taking them directly from this bath as they are needed. Swabbing out the vagina with an antiseptic solution applied by means of cotton held in a dressing forceps is superior to using a douche alone, but the combination of the two is still better. If, in the presence of retained secundines, curettage is for some reason contraindicated or otherwise undesirable, repeated tight vaginal packing with aseptic or antiseptic gauze, supplemented by one or two hypodermic injections of pituitrin, will accomplish the same result. It is my custom to give pituitrin immediately before undertaking a curettage, instead of afterward, as is more commonly practised. By causing rapid and profound contraction of the uterus it reduces to a minimum any bleeding which may be taking place—often a very important consideration—facilitates prompt evacuation of the uterus by folding or puckering up and detaching the ovum so that it is easily reached by the curette or placental forceps, and tends to harden the uterine wall so that it offers more resistance to the curette and so also minimizes the danger of perforation.

A sharp curette is, in my experience, preferable to a dull one, especially in cases of sapremia. An exception to this is in cases of parametritis, where the secundines have undoubtedly been absorbed, or the trouble has advanced beyond the stage where local treatment of this sort would be of any avail, and interference might be productive of grave injury.

We use the curette to remove retained or infectious material, and while the dull curette, it is reasonably argued, may not open up new avenues of infection, it will not accomplish the results desired, as it merely glides over the surface of the relaxed uterus and has no effect on the uterine contractions. The sharp curette, on the other hand, if used with care, will remove the infectious material and in addition the very action of the curette upon the uterine wall will have a stimulating effect upon the contracting power of the uterus. Here I wish to add that the sharp edge of the curette on account of the curve of the tip or the bend of the shank, has an eccentric slant toward the distal or proximal direction and this helps to prevent cutting into the uterine wall. The concave intrauterine surface has a similar influence. When a dose of pituitrin has preceded the curettage, further contraction will be stimulated which will facilitate uterine emptying, and will help to clear out the infective material filling the sinuses which are so often present in these cases. Blood lost at this time will have a general depleting effect upon all the pelvic organs. A uterus thus contracted with sinuses obliterated will act as a barrier against further absorption into the circulation and any secretion or toxic material that might still be present will find its natural exit. With a chronic subinvoluted or fibrosed uterus there may be little or no contraction and retraction even after it is completely evacuated or apparently so. Such cases may also be followed with pituitrin. When I have finished the curettage I swab out the uterine cavity with undiluted tincture of iodine applied by a saturated absorbent cotton swab held in a uterine dressing forceps. I consider this far superior merely to inserting and shortly removing iodine saturated gauze. When a uterus has been thus treated there is very little chance of infectious material being left to be absorbed into the circulation.

Frequently, if the uterus is imperfectly emptied, whether spontaneously or after curettage, the patient will continue to have a show of blood, and the cervix will remain partly open. The uterus will be relatively large, and have an edematous (not cystic) feel on palpation. This state will continue until the secundines are absorbed or discharged piecemeal, but if this fails to take place the bleeding will usually end with the first regular menstruation following the abortion or curettage. In these cases if one would go deeply into the history he would, as a rule, discover that something was taken or done to terminate the pregnancy. The time of onset of menstruation is very irregular, ranging all the way from one to eight weeks in different patients, and during this menstrual period bleeding may be more profuse than usual, frequently assuming hemorrhagic proportions. In some cases bleeding will continue for months and only be stopped by recuretting, especially if we are dealing with a fibrosed or hypertrophied uterus. Ergot seldom helps in these cases, except to diminish the bleeding temporarily. Pituitrin will prove somewhat more serviceable as it causes stronger uterine contractions, but these contractions will not expel or even separate the retained secundines, if they are strongly adherent, as is usually the case. If the uterus is not hypertrophied or fibrosed, repeated vaginal packing and hypodermic injections of pituitrin will ordinarily take the place of curettage.

THERAPEUTIC ABORTION.

I once assisted a well known gynecologist in curetting a patient three months advanced in her first pregnancy. Irregular bleeding had continued for about four weeks, and the uterus had only attained the size of a nine or ten weeks' gestation. While curetting it was found to be a case of *uterus septus*, the septum being broken by the manipulation of the curette. The patient has since given birth to two full term children. When the operator withdrew the curette I suggested that he had not finished; to which he answered, "Didn't you hear the grating sound?" I contended that the sound was not sufficiently "grating," and more significant still, the uterus had shown no signs of contracting. I had observed that the last stroke of the curette penetrated almost as deeply as his first one. When he suggested that I demonstrate my meaning, I took the curette and after removing a considerable quantity of residual tissue, a more decided grating sound was elicited which was not only more clearly audible but was also palpable and the uterus immediately contracted about an inch in all its diameters. My chief at once admitted that I had been able to teach him something about curettage, and recently—more than nine years later—he repeated this admission.

When a therapeutic abortion must be done, it is well to wait until the uterus is sufficiently softened, as the cervix will then dilate more readily, and if dilatation is carried out slowly and only very gentle force employed, there will be much less cervical trauma and pelvic shock. The uterus will also contract more readily and perfectly during the emptying process, and remain fully contracted, and thus the socalled reaction which sometimes follows curettage and which is often mistaken for infection will be obviated. In a congenitally flexed and unyielding uterus the dilatation must overcome this condition of flexion; otherwise, the secundines in the space above the flexion cannot be reached by the curette, in some cases sufficient tissue being left to continue the pregnancy. It makes no difference whether the flexion is located in front or behind, except that if it is behind and the uterus is also adherent it will increase the size of the impenetrable area.

When the uterus fails to contract although the corpus and fundus are apparently clear, judging by the amount of material removed and the grating sound elicited; or the contraction is insufficient and profuse bleeding continues; or during the operation, the curette encounters a soft, nonresisting, nongrating bed of tissue at or above the internal os, which proves very difficult to remove, it indicates either that flexion has not been overcome, or that the membranes encountered are exceptionally adherent. In either case satisfactory curettage can be obtained by still further dilatation, and giving especial attention to dislodging the tissues in the unyielding area above the flexion. Increasing the bend of the shank of the curette near the tip is of great service. If no pituitrin has been given before the intervention is begun, we may find ourselves confronted by a soft uterus in a profusely bleeding patient, with the ovum coming away very slowly, or possibly no progress whatever being made because the uterine wall offers little or no resistance to the curette. In such a situation pituitrin should be administered and the curette applied to the lower half of the uterus with a lateral and rotary stroke and a downward stroke, withdrawing the curette to the outside of the external os at every downward stroke. After this has been done systematically and completely all around, the ovum should be further loosened at the fundus, and as much as possible of it removed with the instrument. Failure to contract means that the area at or above the internal os has not yet been completely evacuated. In this area the membranes are usually more adherent than in any other part of the uterus, but when it is denuded as far down as the endometrium, the added stimulation to contraction at the internal os, which is effected by curettage, will cause a firmer contraction of the uterine wall so that it will offer sufficient resistance to the instrument to enable one to peel away the ovum. At first, uterine contraction will simply be manifested by this hardening of the uterine wall, but as the emptying process proceeds there will be a noticeable diminution of intrauterine space. When the secundines are completely loosened and the uterus is almost empty, a healthy uterus will now complete its contraction rapidly which is evidenced by the increased flow of blood, the sudden diminution in the size of the uterine canal and the cramplike pain which the patient experiences for a few minutes and occasionally for a much longer period. Curettage for hyperemesis gravidarum, if not done too late, gives instant relief; many patients feel the relief even during the process of curetting.

BALLOONING OUT OF THE UTERUS.

Occasionally we encounter a very soft and cystic uterus, the size of which is out of proportion to the duration of pregnancy, with walls excessively infiltrated, or distended by an unusually large amount of liquor amnii. Under such conditions, especially about the end of the third month of gestation, we may encounter a cervix which will dilate so easily that practically all one has to do is to estimate the extent of dilatation present. In any case where the cervix dilates in this way we are likely to encounter excessive bleeding. When the curettage is being attempted the operator may not succeed in reaching the fundus, or he may reach it at first but lose track of it a short while later, and may even fear that he has perforated the uterine wall, so that the tip of the curette is in the abdominal cavity. Such a condition has been described as ballooning out of the uterus.

I have observed eleven cases of therapeutic abortion where this condition was present, and it was noticeable that all the patients were highly neurotic. Ten were blond or of light complexion, and one was very dark, and all were greatly worried over their condition, or its probable outcome. My explanation of this peculiar uterine condition takes into account the patient's psychic state, some organic disease on account of which the abortion is indicated, and, possibly, the effect of the anesthetic (six had anesthesia), added to the physical peculiarities of the uterus itself, as outlined above. The constant relaxation and contraction of the uterus goes on throughout pregnancy and during a dilatation the nerve control of that organ may be temporarily suspended, so that it fails to contract naturally and will "balloon out," partly at the expense of the constriction and flexion at the internal os, and the tapering lower segment of the corpus uteri, and partly on account of the general softening of the uterus. While some of these patients have not been catheterized prior to curettage, it is possible that a full or partly full bladder was also one of the causative factors.

We shall then see come to pass in a few seconds what normally requires three or four months for Nature to accomplish. It is possible to perforate the uterus during the stage preceding the ballooning out, but no further in extent than the width of the curette's tip. The operator who does not lose his head will realize that it is impossible to strip away the entire fundus and upper portion of the corpus and by tilting the curette in different directions he will soon encounter the uterine wall. They were all associated with more or less profuse hemorrhage. Although the condition has every appearance of being a very grave one, the patient's only reaction with moderate hemorrhage will be a slight acceleration of the pulse rate, when one would be led to expect extreme shock and possibly collapse. In four of these cases, where bleeding was profuse, the patients presented symptoms of dimness of vision, yawning, faintness, and passing of flatus, with rapid and thready pulse. They all quickly rallied as soon as the uterus was completely evacuated. Less extensive ballooning, when one does not lose track of the position of the fundus, is not uncommon in obstetrical practice.

It will be quite useless to attempt to continue the curettage, however, as the instrument will merely glide over the soft yielding uterine wall, and produce nothing except an increased flow of blood. An injection of one c. c. of pituitrin should be given, and its action awaited before continuing the operation. Resume curetting from a convenient height without looking for the fundus, using a downward stroke and bring the instrument frequently outside the external os. As the contents are removed the uterus will contract, and the fundus descend of itself, as in any other case. Should one c. c. of pituitrin fail to bring about the desired hardening of the uterine wall, the dose may be repeated, or one c. c. of ergot given. Such an outcome can usually be avoided by giving the pituitrin before undertaking the curettage.

Except in primiparæ, the use of anesthesia can usually be avoided, a little tactful management and cheerful reassurance on the part of the operator being all that is necessary. If the patient is conscious, when the uterus balloons out or contracts sluggishly, she can be directed to make use of the abdominal muscles and by bearing down strongly, the uterus can be made to contract temporarily, and the curettage be continued during the straining movements, as all that is really necessary in the vast majority of cases is to peel away a few portions of the ovum until the endometrium is laid bare, whereupon the uterus will begin to contract. This is especially effective near the internal os. When no anesthesia has been employed the patient's respirations after a short while will become slow and shallow, due to the fear of pain, and the reflexes incident at this time from the slight gnawing pain actually caused by the monotonous movements of the curette, added to other psychic causes. This respiratory factor undoubtedly has an influence in delaying contraction and favoring relaxation. Give the patient two or three minutes' rest, and she will draw one or two deep sighing respirations which will be followed by normal breathing. If curettage is then resumed the uterine wall will be found firmer and the contents will peel away more readily. In a few cases several such rests may be necessary, even if the pituitrin injections and the bearing down movements have also been employed, before we can bring the operation to a satisfactory conclusion. The practice of swabbing out the uterine cavity with pure iodine is always followed in these cases, but I never make use of a uterine drain or vaginal pack, nor employ an intrauterine douche. I have seen many cases of trigonitis and general cystitis following a curettage which was done in the presence of a distended bladder. The importance of seeing that the bladder is fully emptied before beginning to curette needs no emphasis.

1851 SEVENTH AVENUE.

Gumma of the Cervix Uteri*

By HARRY A. DUNCAN, A.B., M.D., F. A. C. S.,
Philadelphia, Pa.

My object in this brief paper is not to tell you something new about syphilis of the cervix uteri, but to point out some old lessons which the experience of the last year leads me to feel are being overlooked. Carcinoma of the cervix, especially a large cauliflowerlike growth, is being diagnosed at the present time by a large number of medical men without the use of the microscope. The well known danger of metastasis from manipulation and especially from the removal of a section of tissue for microscopic examination is the explanation. So much is the dissemination of this local disease feared by many surgeons that in applying radium they will not dilate the cervix even enough to receive the radium capsule.

Men like Bloodgood have taught us to look for carcinoma in an old specific lesion of the tongue. They have told us that one of the chief causes of carcinoma of the tongue is an old specific lesion. Perhaps the same intimate relation between syphilis and carcinoma in the cervix does not often present itself, but I am of the opinion that such a relation does exist and is often overlooked. I present herewith a few brief case histories for consideration.

CASE I.—The patient, Mrs. C., had just had a profuse vaginal hemorrhage when I was called in to see her in April, 1922, and I found a minister at the bedside administering the last rites. She presented all the symptoms characterizing a severe loss of blood. From the husband I gathered a few points in the history of her illness. The family doctor was ill and they had called me in the emergency. One year previously the family doctor had told the family that the patient was suffering from inoperable carcinoma of the cervix, and this diagnosis had been confirmed by a surgeon who applied radium in June, July, and November, 1921. I do not know the amount given. A hurried examination revealed a large cauliflowerlike mass filling the vagina and vesical and rectal fistulæ, either one large enough to admit the tips of two fingers.

---

*Read before the Samaritan Hospital Society, May 14, 1923.

The case seemed so hopeless that little treatment was attempted. The foot of the bed was elevated and a pint of normal saline given under the skin. To our surprise some improvement followed. In a few days the patient was strong enough to be questioned. Only one other fact of any importance was elicited. She had been married twenty-five years and had given birth to four stillborn babies. To withdraw even a small amount of blood for a Wassermann test did not yet seem justifiable but .45 gm. of neoarsphenamine was administered and repeated every week for ten weeks.

The large mass disappeared from the vagina, there was no further loss of blood, and the patient's general improvement was so marked that, despite the annoying fistulæ, she went to church and took daily walks of several blocks. About this time edema of the feet and legs was noticed. It was impossible to secure a good specimen of urine. Four months after I first saw the patient, on her return from a long ride in the park, uremia suddenly developed and she died.

I begged for a postmortem and obtained permission for a partial autopsy. I found the right kidney about half the normal size and very fibrous. The left kidney was entirely destroyed, only a small cyst remaining. There was no evidence of carcinoma in the liver, lymphatics or elsewhere. Only a small portion of the fundus uteri remained. Macroscopically it presented a normal appearance, but microscopically Dr. Clark found carcinoma.

Case II.—The patient, Mrs. O., was referred to me two years ago with the diagnosis of carcinoma of the cervix. On the posterior lip of the cervix was a cauliflower growth the size of an English walnut which bled freely. Pressure with gauze controlled the bleeding. This aroused my suspicion. In her history she had told me she had four children living and well, but on going over the history again I learned that her first two pregnancies resulted in stillbirths at about the seventh month. Wassermann test was four plus. Syphilitic treatment caused the cervix to become normal in appearance.

Case III.—The patient, Mrs. W., when I first saw her six months ago, was extremely pale, semicomatose, and seemed to be in a dying condition. The family doctor said she had returned from a neighboring hospital one week before where she had received her third radium treatment for carcinoma of the cervix uteri. The husband stated they had been married ten years, and she had been pregnant but once. This resulted in a stillbirth. Despite the fact that she had had three radium treatments the cervix was large, spongy, and friable. The os admitted the finger tip. The whole uterus was large and fixed. I suggested a Wassermann. In a few days the report came back four plus. She was given three doses of neoarsphenamine. For some reason her teeth all fell out. She had no further bleeding and was able to go about though her condition was still bad. I have seen her but once since and cannot state what has happened to the cervix.

Partus Serotinus

By W. A. NEWMAN DORLAND, M.D.,

Chicago.

Prolongation of pregnancy to approximately ten and a half to eleven months is not so frequent an occurrence as to warrant its dismissal without comment. In the case herewith recorded an interval of 368 days elapsed between the dates of the last menstruation and the delivery of the child. Allowing the usual three weeks, or twenty-one days, as the interval following the last menstruation in which conception might not have taken place, we have left 347 days. If we allow another six weeks or forty-two days for the irregularity previously noted in the menstrual history of the patient, we still have left 305 days for the duration of the pregnancy—that is, thirty days or four weeks over the average length of gestation. The unusually large dimensions of the infant's head, as accurately determined on the day of delivery, corroborate such a period of prolongation of intrauterine growth. The history of the case is as follows:

Case.—Mrs. S. J., primipara, aged twenty, was born in Turkestan, Asia, of Jewish extraction, and had been married two years. Puberty occurred at thirteen, but menstruation had never been regular. The patient stated that she would at times miss two or three months. Her last menstruation occurred on December 12, 1921. She experienced considerable nausea and vomiting about Easter, which occurred toward the end of March. She could not recall the date of quickening but thought it was about June 1st. Since then there had been active fetal movements. Her health was perfect; she had normal blood pressure and urinary findings, but for the last few days there had been slight swelling of the ankles. The week before she came to me she had visited the Lying-in-Hospital and was told that she should have an immediate Cæsarean section. Her physician, Dr. E. H. Slott, brought her to my office on December 9, 1922. Examination revealed great distention of the abdomen which was drumlike in its rigidity, with fetal movements easily palpable and visible. The fetus lay in the second position of the vertex presentation, its head, appreciably larger than normal, resting in the false pelvis and projecting over the pelvic brim. The x ray plates taken by Dr. M. J. Hubeny confirmed these findings. The fetal heart tones registered 140. Pelvimetric examination showed a normal Baudelocque's diameter with a slight transverse contraction of the brim of the false pelvis, the interspinous diameter being twenty-four and a half cm. and the intercristal diameter twenty-eight cm.

The patient was advised to wait another week, at the expiration of which time, if she did not spontaneously fall into labor, a Cæsarean section would be performed. Five days later labor pains began at one o'clock in the morning and at four o'clock the operation was made through high supraumbilical and fundal incisions. A living male child was delivered weighing ten pounds and presenting the following dimensions: Circumference of the head at the level of the parietal bosses, fourteen and a half inches (thirty-six cm.); biparietal diameter, eleven and a half cm.; bitemporal diameter, ten and a half cm.; trachelobregmatic diameter, fourteen and a half cm.; occipitomental diameter, twenty-two cm.; frontomental diameter, nine and a half cm.; length of the fetus, twenty and a half inches (fifty+cm.); weight of the placenta, thirty-two and a half ounces (two pounds one half ounce). There was about the average quantity of liquor amnii. The apparent disproportion between the length of the child and the size of the head could be accounted for by the father's build. He was a short Jew, but slightly over five feet in height, and with an unusually large head development.

The average duration of pregnancy is from 272 to 280 days, but probably, in about six per cent. of pregnant women this, as von Winckel has shown, may be extended to over 300 days. Duncan remarks that in some of the cases of undoubted prolongation of pregnancy the child is no longer than one at full term, although it may attain an enormous size. Murray records a case in which the interval between the cessation of menstruation and delivery was 330 days, Velpeau one of 310 days, R. Wilson one of 348 days (eleven months, fourteen days), and other authors cases in which the interval was just eleven months.

25 East Washington Street.

Meddlesome Obstetrics*

By JAMES R. McCORD, M.D.,
Atlanta, Georgia,
Associate Professor of Obstretics, Emory University.

It is a matter of common knowledge that, in the vast majority of cases, the bad results obtained in obstetrics, as ordinarily encountered in general practice, are caused by meddlesome midwifery.

If the man who is to do general practice is given a thorough groundwork in the mechanism of labor, and if he is the possessor of an ordinary amount of common sense, obstetrics will lose most of its terrors and mysteries for him, and his results will be incomparably better than those of his brother who does not know the mechanism.

For years I have stressed the fact and taught students that so long as the mother is in good condition, the membranes unruptured and the fetal heart sounds good, there are no indications that will demand active interference. The pleadings of the patient or of her family should never throw the obstetrician off his equilibrium and cause him to interfere needlessly.

CAUSES OF DELAYED LABOR.

A full bladder is, in my opinion, the most common cause of delayed labor and one that is overlooked a surprisingly large number of times. The frequent micturition which occurs during labor should not throw one off his guard. If the patient cannot void, and if there is any doubt about the bladder's being empty, she should be catheterized. A rubber and not a glass or metal catheter should be used for this purpose. Many cases of poor contraction and retraction observed after the third stage of labor, accompanied by bleeding, are caused by overdistended bladders.

The occipitoposterior positions are, in my experience, meddled with unnecessarily more often than any other obstetrical condition. The causes of these positions are the factors of an almost constant first stage delay. The patient becomes worn out on account of painful, irritating contractions and lack of progress. There is delay in dilatation and effacement of the cervix. Pituitrin is contraindicated here, and if morphine is given for effect, it is much better treatment than premature meddling. I have found that the best way to quiet the family is to quiet the patient.

Dilatation of the cervix alone cannot be considered, but must include effacement. The impatience universally displayed by doctors, and the meddlesome interference before there is complete dilatation and effacement of the cervix, account for an enormous number of poor obstetrical results in both mother and child. It is easier to do a manual dilatation on paper than on a woman. The dilatation of the cervix can be carried out manually to a point where delivery of a full term fetus can be done; but complete effacement cannot be done manually, and a full term baby cannot be pulled through a cervix before effacement is complete without great damage. Many women are invalids today from this one phase of meddlesome obstetrics.

I believe I am correct in stating that the Braxton-Hicks version is the method of treatment most universally employed in placenta previa. It is meddlesome and not without grave danger to complete delivery immediately when the cervix is not fully dilated and effacement is not complete. Fortunately, this is not always the case. I do not mean to say that the conditions demanding such a procedure never arise; they do, but very infrequently, and such a procedure, in the great majority of cases, is meddlesome.

I have often stated that to obtain an estimate of a man's real ability in obstetrics, it is necessary to

---

*Read before the Emory University Alumni Society, June, 1922.

watch him conduct the third stage of normal labor. Meddlesome midwifery is a powerful influence here. If I ever succeed in gaining enough obstetrical knowledge to write a textbook, in it no mention will be made of Credé's method of expressing the placenta. No doubt there are indications for its use; but the majority of students get the wrong conception of it, and "meddlesome obstetrics" uses it as another means to prevent good results. I do not believe in putting a time limit on many conditions in obstetrics; but if, after the birth of the child, thirty minutes were allowed to elapse before efforts were made to express the placenta, there would be fewer cases of postpartum hemorrhage, fewer subinvolutions and fewer prolapsed uteri. If left alone, the placenta will always drop into the lower uterine segment when Nature has separated it, and it can then be gently expressed by DeLee's method of early expression. The placenta separates by the alternate contraction and relaxation of the uterus. Constant massage of the uterus during the third stage of labor prevents the necessary relaxations, and defeats the purpose in a normal labor. The hand should be placed lightly on the abdomen, so as not to lose the uterine contour. Personally, I do not invade the uterine cavity for shreds of membranes and small pieces of placenta.

I admit that the general practitioner must conserve his time; that he cannot sit with obstetrical patients as other men do who specialize in this line of work. It is important that the man doing general work should know accurately the progress of labor. I think this knowledge is much more safely gained by rectal than by vaginal examinations. If in doubt about the normality of the case and vaginal confirmation is needed, then do the vaginal examination. I have never yet done a vaginal examination, during labor, through an unshaven vulva and without rubber gloves. Doctors speak freely about the mortality in cases of puerperal sepsis, but little is heard about the morbidity.

Some authorities advise the routine prenatal care of the nipples, in various ways, to get them in a soft and supple condition for nursing. I have always considered this routine method "meddlesome obstetrics." The only exception I make is in cases of inverted nipples. I have never seen a case of breast abscess in which a history could not be obtained of sore, fissured or eroded nipples. The moral is, no fingers, absolute cleanliness, and a nipple shield, upon the first evidence of tenderness.

The mammary engorgement that occurs about seventy-two hours postpartum is not, as so many doctors think, the engorgement of milk but a venous and lymph congestion. A tight breast binder, an extra baby borrowed from some neighbor, or even the ancient proverbial puppy, can all be classed as meddlesome obstetrics. A saline, an ice bag, possibly codeine for pain, may be given. These three simple measures usually suffice for prompt relief. Binders are indicated only when the breasts are heavy, pendulous, and swing down over the curve of the ribs, the ribs interfering with the circulation, causing stasis. A folded towel is placed at the sides of the breasts, and a loose binder holds them on top of the chest. Drying up the milk secretion by a tight binder, breast pumps, etc., is wholly unnecessary. A saline laxative and small doses of codeine are all that is needed for this uncomfortable period, which lasts about thirty-six hours.

I have always taught that the use of vaginal douches during pregnancy was meddlesome. The one exception to this rule is in the case of an active gonorrhea. The traditional early postpartum douches are not indicated. In occasional cases of sapremia and septic infection I use low vaginal douches. I never rupture membranes artificially.

The resuscitation of newborn infants by the methods of Byrd, Schultz, and Prowchownick are to be condemned as meddlesome. I have seen, in autopsy, as the result of these methods, a ruptured spleen, and ruptured liver and kidneys. Simple inversion and letting the baby alone until the cord ceases to pulsate are usually all that is necessary. The mucus may be drawn from the posterior pharynx and trachea by a rubber catheter. It is very necessary, in the treatment of these cases, not to allow the baby to get cold. If artificial respiration becomes necessary, I prefer the mouth to mouth method.

The application of forceps to the unengaged head is not only meddlesome but obsolete. Forceps should not be applied until the head is engaged and the cervix dilated and effaced. In addition to these conditions I always try to wait for anterior rotation of the occiput. Disregard of these facts is the cause of many stillbirths and cranial hemorrhages in the newborn.

It is an indisputable fact that the Cæsarean operation is being abused. Do not do it just because it is the easiest way out. The mortality from this cause is higher than from abdominal sections performed for all conditions. The general surgeon, acting as an obstetrical consultant, often does the operation unnecessarily through lack of knowledge of obstetrical details.

Pituitrin is used by many doctors as an aid in their practice of meddlesome obstetrics. I am absolutely convinced that this drug, as ordinarily administered, is dangerous for both mother and child. Briefly stated, I think the following are indications for its use:

1. The cervix must be dilated and completely effaced.
2. The head must be through the cervix, with anterior rotation of the occiput.
3. There must be no disproportion between the fetal head and the maternal pelvis.
4. There must be uterine inertia: never unnecessarily whip up a hardworking uterus with any oxytocic.
5. The dose should be small, three to five minims, repeated if necessary.
6. Pituitrin can be given immediately after the birth of the child to control hemorrhage and hasten the third stage of labor, upon good authority.
7. Pituitrin should never be used in abnormal presentations.

I am fortunate in having enjoyed a wide experience in obstetrics, and, as a result of that experience, I plead for a more universal acceptance of the following:

1. Learn thoroughly the mechanism of labor.
2. Never interfere with any labor that is progress-

ing normally. A slow labor is not an abnormal labor.

3. A full bladder is the most common cause of dystocia.
4. Pituitrin is a dangerous drug.
5. Do not rupture the membranes artificially.
6. Practice conducting labors by abdominal examinations.
7. Conserve the anatomical parts of the patient, not your time.
8. A greater proportion of women in labor need sedatives rather than oxytocics.
9. Manual dilatation and effacement of the cervix is not possible.
10. Treat occipitoposterior positions expectantly, as long as you think possible to do so, then just a little longer.
11. A version performed for hemorrhage, through an undilated and uneffaced cervix, must not be completed.
12. Manage patiently the third stage of labor.
13. Nipple trouble always precedes a breast abscess.
14. Douches are contraindicated.
15. Apply forceps after mature deliberation; never too soon.
16. Violent methods are never necessary in the resuscitation of the newborn.

20 East Linden Avenue.

A New Theory of Menstruation

By ANNE YOUNG, M.D., Dr.P.H., D.T.M.,
Tallahassee, Florida,
Professor of Hygiene and Resident Physician, Florida State College for Women.

The previous theories of menstruation may be grouped around a few main ideas as follows: first, that it is a cyclic throwing off of a portion of the endometrium; second, that it is due to the maturing of a Graafian follicle with the resulting corpus luteum; third, that it is caused by an internal secretion; still another, that it provides a rich pabulum to nourish the embryo. This article presents the possibility that menstruation may be a function established to provide blood albumen as support and possible nourishment for an ovum during the predecidual period.

A study of the life cycles of many disease bearing insects has brought out the fact that ova are never stationary. A certain degree of rotation seems to be a biological need, for example, the anopheles mosquito selects vegetable matter in a watery incubator. She places her eggs in designs referred to as floats. The culex mosquito selects a different pattern, she makes a raft. The yellow fever mosquito "lays eggs singly in small irregular groups some distance above the water. They are laid in from one to seven days after the female has fed upon blood," and usually after successive blood meals.

We find that the following places are selected as suitable positions for the development of fertilized ova of insects: quiet waters, grass blades, water lilies, the under side of leaves pieces of stick, rocks, hairs, threads, etc. In the case of frogs the ova are laid singly or in small clusters, while toads lay them as long unbroken strings and in each case they maintain this original design until such time as their development reaches a stage when the individual embryo can exist independently. The ova of many of our disease bearing insects are deposited in masses. Many fish ova are deposited in the water and are fertilized there. Where the ova are discharged in masses they are held together by a gluelike substance and even when each is deposited separately it is attached by a gluelike substance to some support. Take as an example the head louse, which deposits the egg on a hair or thread and cements it there.

In the study of chick embryology it is found that the eggs in the incubator must be rotated twice daily for a certain number of days in order to prevent deformities. The hen does the same thing for the eggs in the nest. It is only when the fertilized hen's egg is placed under proper conditions, and not till then, that segmentation begins.

Many insects protect their eggs with a gelatinous substance. It is known that the ovum of many animals become surrounded by a gelatinous covering. In rabbits this envelope becomes enormously thick about the blastodermic vesicle: and this is the stage, we are told, when the human embryo is supposed to reach the uterus.

All ova are of such a shape that a rotary motion can be carried out with a minimum of jar. Nature is extravagant in the extreme when it comes to the perpetuation of a species—she does nothing purposeless or useless.

The few instances cited suggest, 1, that ova are generally protected or supported by some kind of an adhesive or gluelike substance, and 2, that a limited amount of movement is essential to prevent deformities.

Perhaps you are asking how this has anything to do with menstruation? In textbooks the term implantation is used to describe the manner of the embryo's attachment to the uterine mucosa. One textbook goes so far as to say, "That the human embryo penetrates the mucosa as would a parasite." Let us suppose that fertilized ovum is discharged from the fallopian tube into the uterus, it is nothing more than reasonable to conclude that the menstrual function has had some share in preparing for its reception.

Menstrual blood we know differs from blood from other sources in its normal noncoagulability. Why this is so no one has as yet satisfactorily explained. Something may have been added, something may have been held back. In the hours while the decidua are developing could anything support, protect or permit motion of the ovum better than blood albumen? The albuminous cradle of the chick embryo may have its counterpart in the human provided by blood albumen during the first hours of intrauterine life.

The position of the human subject is such that special provision needs to be made for the protection of the ovum during the period when its existence purely from a mechanical standpoint is precarious. If this theory has any basis of fact in it one can readily see that any deviation from normal blood (such as is found in syphilis) would have a profound influence on the developing ovum.

By way of a summary let us define menstruation as a function established to meet the biological requirements of fertilized ova.

An Analysis of Twenty-Six Extrauterine Pregnancies*

By CHARLES MAZER, M.D.,
Philadelphia,
Assistant Gynecologist to the Mt. Sinai Hospital of Philadelphia, Instructor in Gynecology, Graduate School of Medicine, University of Pennsylvania.

It is with an apology that I venture to add this brief analysis to the already overburdened literature of ectopic gestation. There are, however, in this small series of cases, interesting observations which seem to me to be well worth recording.

CAUSES OF ECTOPIC PREGNANCY.

Conditions giving rise to primary sterility are no longer held to be the most important factors in the causation of ectopic gestation. Through the aid of the Rubin apparatus, we (1) have found through studying a large number of cases, that almost fifty per cent. of these women have nonpatent fallopian tubes—a condition precluding the possibility of pregnancy in any form.

A. J. Rongy (2) found that in his series of one hundred cases, seventeen women had not previously been pregnant. In H. F. Lewis's (3) series of one hundred and sixty-eight cases, only sixteen women gave a history of primary sterility for five years or more. In a study of one hundred and seventeen cases, Foskett (4) observes that twenty-seven patients had not previously been pregnant. Averaging these figures, it is found that approximately fifteen per cent. of the patients in whom ectopic gestation exists have not previously been pregnant. McKenzie, cited by Schumann (5), gives the same ratio in a series of one hundred and fifty cases. In our series of twenty-six extrauterine pregnancies only two patients had not previously been pregnant.

The large number of ectopic cases in which there have been one or more abortions is striking, especially when it is remembered that the statistics are taken from hospitals situated in large industrial centres, where there is a large proportion of induced abortions with resultant adnexal disease.

In Hartman and Bergeret's (6) reported cases, of the one hundred and forty-nine patients who had previously been pregnant, forty-eight had had at least one abortion. In Foskett's (4) series of one hundrèd and seventeen cases, about one third of the patients had had previous abortions. About one half of our patients had had previous abortions, many of them admittedly induced. Abortions and their sequelæ seem a more common cause for the development of ectopic pregnancy than venereal diseases. C. M. Enchols (7) believes that the increase in ectopic pregnancies is not due to an increase in venereal diseases, but rather to induced abortions and low-temperature vaginal douches undertaken for birth control. M. O. Magid (8) ably contends that a spreading endocervicitis is at the root of the pelvic disease that causes extrauterine pregnancy.

The following conditions bearing on etiology were found in our series: Previous ectopic gestation, one; ovarian cyst on the affected side, one; induced abortions, four; spontaneous abortions, nine; previous inflammatory conditions of the adnexa not caused by induced abortions, three; previous operations on the lower abdomen with some adhesions, one.

PATHOLOGICAL CONDITIONS.

All pregnancies in this series were tubal, either isthmial or ampullar, two thirds being on the left side. Eight were unruptured with severe intraabdominal bleeding, thirteen were tubal abortions, with hematoceles, two being badly infected; the remaining five were operated on before rupture. One of these five furnished a beautiful specimen of a three months' fetus in the unruptured tube. One patient had a coexisting intrauterine pregnancy which was barely suspected at the time of operation. The case is sufficiently interesting to deserve recording.

Case I.—Mrs. M. F., aged twenty-three, married four years, the mother of one child, had had previously an induced abortion. She entered the hospital on September 28, 1919, in a state of shock. An immediate laparotomy showed a ruptured ectopic pregnancy with a large quantity of blood in the peritoneal cavity. The uterine body was large and soft, betraying the possibility of a coexisting intrauterine pregnancy. The patient made an uneventful recovery and left the hospital on the fifteenth day. A vaginal examination prior to her discharge from the hospital still further increased our suspicion of a coexisting intrauterine pregnancy. As the woman was not bleeding, she was sent home with instructions to return in two weeks for observtaion. She reported to the gynecological clinic on October 31st with profuse vaginal bleeding. Examination showed a large uterus, a soft and patulous cervix, and an ovum presenting at the internal os. She was put to bed and the uterus was emptied on the following morning.

---

*From Dr. J. C. Hirst's Service at the Mt. Sinai Hospital, Philadelphia.

Cases of simultaneous tubal and uterine pregnancy are extremely rare. Neugebauer, as quoted by M. F. Raunat (9), collected in 1913 two hundred and forty-three cases, one hundred and seven of which were published in the eighteenth and nineteenth centuries and the remaining cases from 1901 to 1913.

When the ovum develops in that part of the tube which traverses the uterine wall, the condition is called interstitial pregnancy—a very rare condition. When it is lodged in the constricted portion of the tube, it is called isthmial pregnancy. When it develops in the outer third of the tube, it is called ampullar pregnancy. When it is expelled from the fimbriated extremity of the tube without rupture of the latter, the condition is called tubal abortion. This process is always accompanied by dribbling of blood from the free end of the tube into the peritoneal cavity, creating a large hematocele, usually in the pouch of Douglas, where it can be felt readily by vaginal examination.

Tubal abortion is frequently accompanied by severe hemorrhage, and cannot, clinically, be differentiated from rupture of the tube. Rarely this mass of blood may become absorbed, more often the hematoceles become infected and form the most extensive and destructive abscesses.

When the overdistended tube ruptures, and the ovum is discharged into the peritoneal cavity, or, as occurs rarely, into the layers of the broad ligament, the classical symptoms of sudden pain, shock, and, occasionally, tragic death, present themselves.

How often rupture of the tube terminates fatally is a matter of conjecture. Polak (10), who does not operate in these cases until the patient has recovered from shock incident to hemorrhage following the rupture, places the mortality at one third of one per cent. But the patients who come under his observation are those who have survived the initial shock, as evidenced by the lapse of time between the rupture of the tube and the admission of the patients into the hospital.

What about those patients who die before the correct diagnosis is made, and whose deaths are wrongly attributed to ptomaine poisoning, acute indigestion, angina pectoris, etc.?

E. A. Schumann, in his classical monograph on extrauterine pregnancy, analyzed Parry's statistics of five hundred cases in which one hundred and seventy-four patients, or thirty-two per cent., perished from hemorrhage following rupture. These statistics refute Hunter Robb's dictum that "the hemorrhage *per se* is rarely, if ever, the sole cause of death." Oastler (11) draws these conclusions:

1. Ectopic pregnancy occurs about as often on one side as on the other.
2. Tubal abortion is most common.
3. Double ectopic pregnancy is very uncommon.
4. The interstitial form may push its way into the uterus and continue to grow.
5. Ectopic pregnancy may occur twice on the same side, because of a failure to remove the whole tube at the previous operation.

When the fertilized ovum becomes implanted in the tube it is destined to early destruction, usually within the first six weeks, rarely after three months. The retention of the ovum in the tube following its death is called a tubal mole.

DIAGNOSIS.

Our records show no single symptom or physical sign common to all cases in this series. An attempt on the part of the tube to expel the contents produces colicky pains on the affected side. This "unrest" on the part of the tube, as J. O. Polak (10) describes it, is transmitted to the uterus, inducing uterine contractions and bleeding. The onset of these symptoms is usually after a missed period, several days after the date of the expected menstruation. The uterus is somewhat enlarged, because it contains a decidua prepared by Nature for the reception of the ovum which failed to reach its destination.

Extreme tenderness with or without a palpable mass is the most constant physical sign in unruptured ectopic pregnancy, and its association with the above mentioned symptoms often led us to a correct diagnosis. We believe that the existence of exquisite sensitiveness to the palpating finger is more important in the diagnosis of unruptured ectopic pregnancy than the finding of a palpable mass, in view of the fact that the latter often proves to be nothing more than an enlarged or cystic ovary. However, a rapid increase in the size of the mass, even in the absence of extreme tenderness, may be accepted as almost pathognomonic of ectopic pregnancy. This rapid increase in size of the mass is not due to a phenomenal growth of the ovum, but rather to extravasation of blood into the tube. This extravasation of blood into the tube usually causes death of the ovum which produces greater uterine bleeding and the expulsion of the decidua for which there is no further use. This is often mistaken for uterine abortion.

An exploratory dilatation and curettage in obscure cases may be of some value, especially when a competent pathologist is willing to cooperate with the operator. In one case we removed through a preliminary dilatation and curettage what appeared to us a degenerated ovum. Pathological examination, however, showed it to be purely decidual tissue. In cases of advanced extrauterine pregnancy, that is of two or three months' duration, the decidua may be eight by four centimetres (5).

We cannot agree with Dr. N. S. Heaney (12) who advocates the advisability of an exploratory vaginal incision in doubtful cases. The laparotomy is subsequently complicated by infection with increased mortality.

Contrary to the general belief among medical men, the majority of ectopic pregnancies never present the classical symptoms of rupture. Most of them end in tubal abortion, which rarely gives rise to the severe internal hemorrhage that marks the rupture of the tube. The severity of the symptoms in ruptured ectopic depends upon the quantity of blood lost, not merely upon the rupture of the tube. It is, therefore, often difficult to diagnose definitely an early rupture with slow bleeding. In these cases we have found repeated blood examinations of great value. The gradual fall in the red cell count and hemoglobin indicates internal hemorrhage.

CASE II.—Mrs. S. S., aged twenty-eight, admitted to the wards of the Mt. Sinai Hospital on March 9, 1921, had one child. She had aborted spontaneously two years ago. Menstruation had always been regular, the last missed period being two weeks ago.

Several hours prior to her admission she began to complain of sharp pain in the right lower quadrant of the abdomen. She was sent in by her family physician with a diagnosis of acute appendicitis. Vaginal examination revealed a slightly enlarged uterus, and exquisite tenderness in the right tuboovarian region wih considerable resistance in the right lateral fornix; but no definite mass could be palpated. The first blood picture, at 9 p. m., was as follows: Hemoglobin, sixty per cent. (Sahli); red blood corpuscles, 3,370,000; white blood corpuscles, 10,000. At 10 p. m. the blood picture was hemoglobin, fifty-five per cent.; red blood corpuscles, 3,160,000; at 12 p. m., hemoglobin, fifty per cent.; red blood corpuscles, 2,500,000; and at 2 a. m., hemoglobin, forty-six per cent.; red blood corpuscles, 2,270,000.

Though the woman still showed no symptoms of shock, it was evident that she was bleeding internally, as no other condition could explain the gradual reduction in the red cells from 3,370,000 to 2,270,000 with a concomitant fall in the hemoglobin from sixty per cent. to forty-six per cent. in five hours. I operated on her at four o'clock that morning, and found a rupture of the right tube with considerable free blood in the peritoneal cavity. The tube and appendix were removed and 500 c. c. of normal salt solution were given intravenously. The patient had an uneventful convalescence.

A high leucocytosis is the exception rather than the rule in extrauterine pregnancy. In one of our cases the leucocyte count reached 24,000 with a polymorphonuclear count of eighty-eight per cent.. There were tenderness and rigidity in the region of the appendix. Pelvic examination gave no positive evidence of ectopic gestation. The patient's menstrual history was most misleading. The preoperative diagnosis was acute salpingitis with involvement of the appendix. The actual condition found on operation was a tubal abortion.

TREATMENT.

As long as it is impossible to foretell how soon the hemorrhage may prove fatal in any given case, I believe it is proper to operate without delay regardless of the state of shock. The latter can easily be combatted during the operation by intravenous salt solution, which may later be supplemented with blood transfusion. J. O. Polak (10) defers operation until the patient has recovered from the shock incident to hemorrhage following rupture. A. J. Rongy (2) followed the same course until he saw two women die without surgical aid. He then modified his course of treatment considerably.

The practice of some surgeons to remove the ovary with the tube in order to hasten the operation is not good judgment. A patient of mine lost the only ovary she had at the hands of one of our most prominent surgeons. It takes only five minutes longer to remove the tube alone and suspend the ovary by suture of the infundibulopelvic ligament. Two of our patients required blood transfusion to combat the marked anemia. In this series of twenty-six cases we had no mortality.

CONCLUSIONS.

1. Primary sterility is not an important factor in the etiology of ectopic gestation.
2. Abortion, especially induced abortion, is a potent factor in the causation of extrauterine pregnancy.
3. Only thirty-three per cent. present the classical symptoms of ruptured ectopic.
4. Exquisite sensitiveness of the unruptured tube furnishes the most valuable sign of ectopic pregnancy.
5. A rapid increase in size of a tuboovarian mass, coupled with marked tenderness, is pathognomonic of extrauterine pregnancy.
6. An exploratory curettage may be of value in the diagnosis of this condition.
7. Frequent blood examinations may be of some value in cases of slow bleeding.
8. Operate immediately and combat shock by intravenous injections of salt solution and blood transfusion.

The Use of Phloridzin in the Early Diagnosis of Pregnancy*

By ALFRED M. HELLMAN, B.A., M.D., F.A.C.S.,
New York.

A sure, safe and simple method for the early diagnosis of pregnancy would, it seems to me, be a welcome addition to our diagnostic armamentarium. The diagnosis of pregnancy at its onset might prove of value from a medicolegal point of view; also for an early interruption of the pregnancy where such interruption is indicated. Naturally, the woman wants to know as soon as possible, perhaps because she merely wants to know, or possibly to help her in deciding some important step, such as going on an extended trip or moving into larger quarters.

The Abderhalden test has rightly fallen into disuse because it requires complicated laboratory methods, and even then is far from reliable. The precipitation of red blood corpuscles is likewise not diagnostic.

That there is a certain amount of need for early diagnosis is evidenced by a study of the literature. Several articles have appeared recently in which decreased sugar metabolism during the early months of pregnancy has been discussed. This has been done chiefly by feeding excessive quantities of glucose to the patient and making elaborate quantitative tests of the blood sugar.

A. W. Bauer (1) asserts that, although artificial glycosuria induced by the ingestion of glucose does not furnish a differential diagnosis between extrauterine pregnancy and tumor of the adnexa, its value must be recognized for the early diagnosis of pregnancy. His method was to test the urine and blood six times at ten minute intervals and twice at thirty minute intervals following the ingestion of excessive quantities of glucose.

---

*Read before the Lenox Hill Hospital Association.

Welz and VanNest, of Detroit (2), reported on seventy-one cases of early pregnancy in which glucose was given per os to produce glycosuria. They concluded that glycosuria was of no prognostic importance in pregnancy but of considerable diagnostic value up to the twelfth week.

Kamnitzer and Joseph, working in Berlin, have tried to show that such a glycosuria can be artificially produced in the early months of pregnancy by the intramuscular injection of phloridzin. In the non-pregnant such an injection should not produce glycosuria, nor is it likely in those pregnant over twelve weeks. During the first three months, glycosuria should appear. It is the technic of these men that I have used and which I shall explain here with case reports and results.

Kamnitzer and Joseph found that the test was most reliable when one c. c. of a two per cent. solution (0.002 g. or 3/100 gr.) of phloridzin was used. The preparation that I have employed is supplied in one c. c. ampoules which contain 0.002 gram (3/100 grs.) of phloridzin and 0.001 gram (3/200 grs.) betaeucaine hydrochloride. An intramuscular injection should be given in the morning when the stomach is empty. Before the injection, the patient urinates and then drinks 200 c. c. (six ounces) of water, or tea or coffee without milk or sugar. If the urine, which was passed before the injection was made, reduced Nylander's solution on being boiled and allowed to cool, the phloridzin test should not be continued. After the injection the urine is passed three times at half hour intervals and each time tested with Nylander's solution. At the end of the first half hour the patient is again given 200 c. c. (six or seven ounces) of the bland fluid.

If the urine passed after the injection of the phloridzin reduces Nylander's solution the patient is supposedly pregnant.

Since such drugs as antipyrine, salicylates, saccharin, chloral hydrate, camphor, chloroform, hypophysis extracts and adrenal preparations sometimes give a positive Nylander test, it is best to see that none of these drugs have been used.

I have made the test twenty-four times on twenty-three patients. In seventeen cases where the tests were negative fifteen patients were found not pregnant but two were later found to be pregnant. In the seven cases giving positive results the patients were all pregnant. I present below my interpretation of the two cases with negative tests in which the patients were pregnant at the time the test was made.

Case I.—Mrs. M. R., aged twenty-two, had stopped nursing her baby early in January, 1923, and had menstruated on January 5th and February 2, 1923. When I examined her on March 5th I was unable to decide as to the existence of pregnancy, so on March 9th I made the phloridzin test which was negative. By March 29th I was convinced of the existence of pregnancy by my vaginal examination, so on April 6th I made another test which was positive. The course of events proved this to be correct. This can be explained in only one of two ways. Either the test was done too early or the case will have to go into the group where the test remains unreliable or unsatisfactory.

Case II.—Mrs. F., aged thirty, denied the possibility of pregnancy as she had been sick with influenza and away from her husband for some time. For over two months she had bled every two weeks for several days at a time and quite profusely. A vaginal examination led me to tell the patient that I suspected pregnancy, but as on the next day the phloridzin test was negative, I felt that I must be dealing with a soft bleeding myoma. On April 5th I operated, but before starting the intended laparatomy I did a curettage and removed large amounts of degenerated placenta and did not have to do a hysterectomy at all. In this case the test may have been negative, despite the presence of pregnancy, because of the death of the fetus, as the pregnancy had advanced more than twelve weeks, or the case may also belong to that ground in which the test will remain incorrect.

Test No. 1—Mrs. L. K., aged forty-one. Menses always regular. Last menses August 24th. Very stout, examination difficult. October 14th, test negative. Because family physician feared to allow a possibility of pregnancy to continue, I curetted October 17th and found the uterus empty.

Test No. 2—Mrs. R., aged forty-four. Always regular. Last menses December 11th. Test made January 14th was negative. Menses appeared next day.

Test No. 3—Mrs. F., aged twenty-nine. Last menses November 22nd. Physical examination showed that she was definitely pregnant. Test January 21st, positive in one hour.

Test No. 4—Mrs. H., aged twenty-four. Last menses December 17th, and then only one day. January 28th, thirty minutes after the injection of phloridzin, the Nylander test was positive. Patient was pregnant.

Test No. 5—Miss B——z, aged thirty-one. Last menses six weeks previous. She had on a previous occasion gone over six months without menstruating but at that time there was no cause for a suspicion of pregnancy. February 23rd, test positive. Later developments proved that she was pregnant.

Test No. 6—Mrs. L——n, aged thirty-three. Not overdue but suspected that she was pregnant. As she was contemplating a trip abroad she was anxious to know. The test was negative and five days later and before sailing the menses appeared.

Test No. 7—Mrs. M——h, thirty-seven. Two weeks overdue. Test positive. Patient pregnant.

Test No. 8—Mrs. K——t, aged thirty-two. Always irregular. Menses four days overdue. Test February 24th negative. Menses appeared two days later.

Test No. 9—Mrs. M. M., aged thirty. Menses frequently absent for months at a time. Two weeks overdue. Test positive. Patient pregnant.

Test No. 10—Mrs. G——y, aged forty-four. In 1917 I removed a left ectopic. Last menses December 19th to 24th. Uterus seemed enlarged. Test made the next day was negative. March 4th menses appeared. She was greatly disappointed as she was anxious to have a child.

Test No. 11—Mrs. H——n, aged forty. Just over period. Test negative. Patient not pregnant.

Test No. 12—Mrs. M. R., before detailed.

Test No. 13—Mrs. L——v, aged thirty-six. Six children. Therapeutic abortion January 13th. Only menses since then on February 15th. Test March 20th was negative. Menses appeared one week later.

Test No. 14—Mrs. B——r, aged thirty. One child. Right cystic ovary removed November, 1921. Last menses February 17th. Negative test on March 26th. Patient was not pregnant.

Test No. 15—Before detailed.

Test No. 16—Mrs. R is the same patient as test No. 12 where the test was negative March 9th and positive April 6th and the patient was pregnant.

Test No. 17—Miss B——t, aged twenty-four. Last menses March 5th and 6th. Test April 14th, negative. Menses set in April 23rd.

Test No. 18—Mrs. Z. Hyperthyroid case. Last menses February 23rd. Always delayed but never as much as this time. Test April 24th, negative. Menses appeared April 27th.

Test No. 19—Mrs. H. F., aged twenty-nine. One child. Menses always delayed two to three weeks. Last menses February 27th. Test May 8th, positive. Patient was definitely pregnant.

Test No. 20—Mrs. H. L., aged thirty-five. Menses as a rule every twenty-eight to thirty days lasting three days. Last menses March 28th. May 11th and 12th slight bleeding. Test May 16th, negative. Patient is definitely not pregnant.

Test No. 21—Mrs. D. F., aged twenty-one. One child nine weeks ago—child died when half hour old so there was no nursing. Menses appeared six weeks ago, the only time since labor. Test May 28th, patient is not pregnant.

Test No. 22—Dr. L.'s patient, aged twenty-four. Married one year. Menses as a rule regular. Now absent two and a half months. Test negative. Two weeks later menses appeared.

Test No. 23—Mrs. M. G., aged thirty-one. One child. Last menses was one week too early when it appeared April 19th. Thin, easily examined, uterus very small. June 1st test negative. Not pregnant.

Test No. 24—Wife of Dr. S., aged twenty-two. No menses for one and a half years during which time she gained forty pounds. Married six months. Maturin test June 2nd. Patient is not pregnant.

CONCLUSIONS.

Healthy, nonpregnant women give negative results with the phloridzin test. Women pregnant less than twelve weeks will as a rule, though not invariably, give positive results with the test. The number of cases here tested is too small to draw definite conclusions or give percentages. Certainly there is something in the test and it deserves further study.

76 EAST SEVENTY-NINTH STREET.

Pus in the Pelvis of Women

By G. PAUL LA ROQUE, M.D., F.A.C.S.,
Richmond, Va.

Among seventeen hundred women studied and operated upon by myself for disease of pelvic organs between seventy-five per cent. and eighty per cent. presented signs, symptoms and visible pathology of inflammatory disease of the uterus and adnexa. In between seventy per cent. and seventy-five per cent. of the inflammatory cases operation was performed essentially for such lesions as lacerated cervix, displaced uterus, tumors of the uterus and ovaries, retained material following miscarriage, and for such tube disease as old adhesions and hydrosalpinx in which active and gross suppuration of tubes was not present at the time of operation. These are not included in this report.

The total number of suppurative cases was five hundred. In three hundred and thirty the pus was confined to the tubes, uterus, and ovaries, and in one hundred and seventy there was walled off suppurative peritonitis in the form of pelvic abscess. We have been careful to exclude every case which, after the abdomen was opened, presented any doubt even to a skeptic at some distance from the table, as to the suppurative nature of the disease. Only and all cases of old fashioned, dyed-in-the-wool pus tubes, suppurative ovarian cysts and pelvic abscesses are included. The pathological picture is too familiar. Pus was present in and about the organs, the peritoneum red, swollen, edematous, and the organs lightly or tightly adherent to each other and to bowel and omentum. The uterus and tubes were the organs primarily involved; no case of appendiceal abscess is here included.

The patients were all acutely sick upon admission to the hospital, suffering abdominal pain of variable severity, tenderness, muscular rigidity over the lower and often the upper abdomen, palpable masses in the pelvis, fever, prostration, and other signs of acute illness from pelvic organ suppuration with peritonitis. Several years ago a study of records showed that all women upon whom we had operated for suppurative disease of the pelvic organs invariably presented, as a part of the pathology, preexisting lesions antedating inflammatory disease.

Of the women in this series with suppurative disease eighteen per cent. had previously existing fibroids of the uterus; forty-two per cent. had ovarian cysts; approximately fifty per cent. had displacement of the uterus; fifteen per cent. to twenty per cent. had lacerated cervix; in several cases there were suppurating hematomata following ruptured tubal pregnancy, and in three suppurating tubes complicating uterine pregnancy.

More than half of the women in this series presented additional surgical pathology apart from that in the pelvic organs. In fourteen the pelvic organ pathology had caused ulceration of the bowel necessitating bowel suture; more than three hundred had definite coincidental appendicitis which of itself needed operation; some had gallstones; some hernia; over a hundred and fifty required operation upon cervix and perineum and rectum; in five per cent. of the women there was present serious secondary anemia ranging from twenty-one per cent. to fifty per cent. hemoglobin; many cases presented heart and kidney disease, obesity, glycosuria and other nonsurgical coincidental affections.

Among the total five hundred women there were four deaths, a mortality of four fifths of one per cent. In no case has operation been postponed more than a reasonable period after admission to the hospital for preparatory treatment and the opportune time. Only one patient has died without operation. This was a woman moribund, with postabortional sepsis, and who died twenty hours after admission. All deaths from all causes are counted. All were in women in whom suppurative disease complicated fibroid and cystic disease of the uterus and ovaries. They are recorded here as deaths from operation for inflammatory disease and also in a recent report of six hundred hysterectomies and ovariectomies for benign tumors.

The fatal cases were as follows:

Case I.—9-1425. The patient was fifty years old, with a left ovarian cyst of large size and of years' duration, and had been acutely sick several weeks and rapidly progressing toward death from suppuration. Upon examination there was found in the left lower abdominal wall an area of suppuration pointing through the skin. Under light anesthesia an emergency palliative puncture of the abscess gave exit to gangrenous cyst material and fecal matter seen to come from the point of adhesion and ulceration of the cyst and sigmoid. She died a few days later of general sepsis. This was in 1909.

Case II.—15-2426. The patient was thirty-five years old, with pelvic abscess, large suppurative ovarian cyst ulcerated into the sigmoid, single pus tube, and pulmonary tuberculosis. Operation consisted of removal of the ovarian cyst and left tube, suture of hole in the sigmoid, appendectomy, and drainage of pelvic abscess. The patient died six weeks later of septic exhaustion and pulmonary tuberculosis. This was in 1915.

Case III.—16-2556. The patient was twenty-five years old with double pus tubes, cystic ovary and pelvic abscess, all acute and erroneously believed to be appendicitis or tubal pregnancy. Hysterectomy, ovariectomy, appendectomy, and drainage of pelvic abscess were performed a few hours after admission, but she died twenty-four hours later of septic shock. This was in 1916.

Case IV.—21-3838. This was a woman thirty years old, three weeks sick with postabortional double pus tubes, pelvic abscess, and cystic ovary. Three days later with signs partially subsided double salpingectomy, partial hysterectomy, ovariectomy and appendectomy were performed. She died the fourth day of septic kidney breakdown. This was in 1921.

In the five hundred cases here reported the women have welcomed operation as a last resort. The clinical story is that of recurrent attacks or alternate remissions and exacerbations of symptoms, periods of encouragement that they may be better, discouragement that for some usually assignable reason they have had a relapse, and finally despair of being able to be cured with "the knife."

With the clinical story so familiar it would seem quite superfluous to urge all women hastily to operation by the threat of impending death from the disease. The advantages of earlier operation are incident to the cure of suffering, prevention of extension of disease, prevention of the necessity for technically more difficult, more radical and more dangerous surgery, on account of complicated pathology in women older and less healthy. Reasonably early operation is conservative surgery; late operation calls for radical surgery, and though it is clearly demonstrated that the longer the patients wait the more organs will have to be removed, and though even for ancient and extensive disease the operation is not likely to be fatal, the disease may terminate fatally in spite of operation in a few cases.

The urgency of immediate operation is an important question. Women rarely receive operation for the first spell of symptoms caused by pelvic inflammation save as a result of an erroneous diagnosis. The great majority of cases of this series were of long postponed operation for complete subsidence of symptoms which refused to subside. Following reasonably long delayed operation and proper preliminary treatment upon previously unrecognized twisted ovarian tumors, ruptured tubal pregnancies, and appendicitis; and following reasonably prompt operation upon pus tubes erroneously believed before operation to be appendicitis, tubal pregnancy, or twisted ovarian cysts, there is low mortality. Lack of conspicuous differences in the results following both plans suggests that after a reasonable wait for sizing up the situation, the time as calculated in hours and days for operation upon women for pelvic disease is of minor importance, as compared to such other factors as the condition of the woman and her abdomen, the preliminary treatment, method of procedure, technic of operation and postoperative treatment. Emergency operation is certainly not needed and is dangerous. A woman too acutely sick to be moved to a proper hospital is too sick to be attacked and will not be operated upon by a surgeon of good judgment. The abdomen of a woman acutely sick with lower abdominal disease may invariably be pacified by morphine and local hot or cold applications and the woman quickly placed in condition for transportation and operation. More than half the women in this series of cases were brought to Richmond from homes in rural districts and towns throughout Virginia and North Carolina. In no case did the trip cause harm; on the contrary, the patients usually seemed better upon arrival at the hospital than before leaving home (morphine administered to make the trip easy helped in other ways).

We have never treated these cases by vaginal incision or "puncture of the *cul de sac*" even for temporary drainage. I have never seen a patient die for want of simple drainage, and but few in whom there was reasonable ground for the belief that puncture of the *cul-de-sac* could have been of sufficient benefit to justify the operation. Once in a while a puncture of the *cul-de-sac* may be followed by the discharge of what appears to be a large quantity of pus, but as a rule the quantity removed is quite small. On the other hand in a large proportion of the cases (between 11.7 per cent. and 25 per cent.) the operation reveals an error of diagnosis or the pus is not accessible. The discovery of blood, an ovarian cyst, tumor of the uterus, or of fecal matter will reveal an error of diagnosis resulting in the necessity for opening the abdomen immediately to remove a ruptured tubal pregnancy, twisted ovarian tumor or some other pathological condition not accessible by the vaginal route and in a woman "too sick for radical abdominal operation."

An added abdominal operation performed as a matter of necessity and urgency upon a woman under these circumstances is a serious danger to the patient. Vaginal puncture, even in the hands of those advocating it, is not intended to be curative but only a temporary benefit in twenty per cent. of the cases, and there is at least six per cent. immediate mortality (1). We have in a large number of cases acted with entire satisfaction upon the theory that patients who could be benefitted through vaginal puncture are benefitted equally by the proper application of the modern treatment of peritonitis; by avoiding purgation and solid food; by the administration of large quantities of water, usually by mouth, but in desperate cases by hypodermoclysis; by the administration of sufficient doses of morphine to give the patient complete rest and pacification of peristalsis.

This standard treatment, endorsed by the great majority of American surgeons at the present time, has been practised in all cases accompanied by fever, great pain, and a distended rigid abdomen as a preliminary measure to operation. Under this treatment we have seen so many easily recognized inflammatory masses of large size completely or almost completely disappear and have never seen a patient die, that it is not easy to see any advantage in vaginal puncture. Though vaginal puncture is made and pus flows we are not justified in hastily concluding that the patient would have died if she had not been punctured. It is easier for surgeon, bystanders, and members of the family to believe this than it is to prove it. With the present day treatment of pelvic peritonitis it would seem that there is scarcely any real need for this procedure. It is often more dangerous than the disease.

A systematic, thorough, operative procedure is called for. In nearly all cases after the woman is anesthetized the final bimanual vaginal examination is made. After cleansing the vagina of gross filth, the iodized cervix is well dilated and a dull spoon curette introduced for exploratory purposes and to remove loose material. In years gone by we usually scraped about in the interior of the uterus. We have never felt any reason to believe that scraping did any good. Curettage of the uterus is now known to be a procedure of such great danger in the presence of suppurative disease that we consider it a gynecological error.

If the cervix was torn and hysterectomy was not necessary we repaired the cervix if it was not much reddened or infected; if badly infected, or if hysterectomy was to follow, we amputated the cervix with the electric cautery knife. This practice was not pursued in the earlier cases and some of the women were annoyed by purulent vaginal discharge after operation. Since we have had satisfactory electric cautery knives we have employed this method of destroying the cervix and the women have had a dry vagina after hysterectomy. We feel quite strongly that infected torn cervices should not be neglected. Such lesions need treatment independent of abdominal disease.

After dealing with the cervix, lesions about the vagina, vulva and rectum are examined and dealt with accordingly. The abdomen is usually opened by a vertical incision at one side of the middle line. In exceptional cases of excessively fat or greatly overstretched and prolapsed abdominal walls, or of large fixed masses, an elliptical crosscut of the abdominal wall seemed to give more easy access to the pelvis and left a good abdominal wall.

Before the pelvic organs are touched or closely inspected, the gallbladder, bile ducts, and stomach are examined; usually both kidneys are felt to see if one may be absent and to detect lobulated kidney and palpable calculi. Inguinal and femoral herniæ are removed by the intraabdominal method and umbilical herniæ are excised by prolongation upward of the vertical incision. The appendix, unless incorporated in the pelvic pus, is removed before the pelvic organ work is done; if suppurating, appendectomy is reserved until the last. In approximately twenty-five or thirty of the cases here reported, appendectomy had been performed by other surgeons before the patients came to us for pelvic disease. We have also operated upon women for appendicitis after they had previously had pelvic disease operated upon by other surgeons. Three or four of the women in this series of five hundred seemed too sick to take the extra three minutes for normal appendectomy.

By proceeding in this manner and curing the non-pelvic lesions before approaching the pelvic disease, the woman is cured of all her disorders, thus being given more nearly one hundred per cent. efficiency of operation; second operations for appendicitis, hernia, lacerated cervix and perineal tears are forestalled, and the operative procedure most likely to be productive of shock is reserved for the last, so that the patient may be put into a warm bed without delay upon the treatment for shock. In dealing with gallstones, however, we have usually, but not by any means invariably, deferred operation upon the gallbladder. In fourteen cases we were compelled to suture openings into the bowel at points of dense adhesions and in one case the bowel had been previously punctured by a gynecologist while puncturing an abscess in the *cul-de-sac*.

One or both tubes were removed in all but one of the five hundred cases here reported. In between eighty-five per cent. and ninety per cent. of the cases both tubes were the seat of suppuration at the time the abdomen was opened. One or the other was frequently found to be enormously enlarged and distended, while the opposite tube was much less extensively diseased. In some of the earlier cases we made efforts at conservatism and removed only one tube. We soon found, however, that while this was preservation it was not conservatism. Some of these women continued to suffer from inflammatory disease, a few returned to us for the second operation, and doubtless others were operated upon elsewhere. Conservatism of healthy structures is quite different from the preservation of diseased ones. For nonsuppurative disease in women of childbearing age we have seldom removed both tubes under any circumstances; but for suppurative disease of such severity as in the cases included in this report, both tubes have been hopelessly diseased in approximately ninety per cent. of the cases.

For the past five years I have invariably removed at least the upper part of the uterus in patients from whom both tubes had to be removed. Close examination of the uteri after removal and cutting through at various places has shown a large proportion of them to be the seat of small though easily obvious abscesses throughout the uterine muscle. Convalescence is much smoother and in my experience the mortality is less; the cure of symptoms is more complete, and postoperative leucorrhea less often noted following partial hysterectomy, when both tubes need removal, than after leaving the inflamed uterus which can have no function.

We have performed hysterectomies on four hundred and sixty of the five hundred women. Removal in one piece of both suppurating tubes and the intervening portion of the uterus at some point between the tube attachment and bladder, makes easy complete covering of all raw surfaces by a continuous stitch from one end to the other of the broad ligament over the uterus.

Subtotal is the type of hysterectomy called for in the great majority of cases showing extensive suppurative disease in which it is necessary to remove both tubes. Preceding hysterectomy in women with large cystic, torn, and infected cervices, cautery amputation of the cervix has proved of great value in destroying the diseased cervix and preventing postoperative vaginal discharge. The small remaining piece of thoroughly cooked cervix after cautery amputation of the cervix from below and subtotal hysterectomy from above, serves nicely as holding material to which the round and broad ligaments may be sutured for suspension and to cover all raw surfaces with peritoneum. This combination of cautery amputation of the cervix and subtotal hysterectomy has so far, in more than one hundred cases, served quite satisfactorily for the cases to which total hysterectomy is advocated by many. Menstruation is not stopped by this method. I have performed the complete hysterectomy from above in a few cases of this series without fatalities and am open to conviction that the total operation from above is no more dangerous and more completely curative than subtotal hysterectomy preceded by cautery amputation of the cervix.

Ovariectomy has been employed in slightly more than fifty per cent. of the women in this series for ovaries and cysts hopelessly entangled in inflammatory exudate, dense adhesions or obviously internally infected; and in cases gangrenous with torsion of the pedicle.

In no case have both ovaries been removed from any woman under forty-five years of age unless all ovarian tissues had been totally and hopelessly destroyed by inflammatory disease and cysts. In approximately ninety per cent. of the total cases we have found it practicable to save some portion of at least one ovary and avoid the production of artificial menopause. This practice has thus far been satisfactory and while a few women have failed to get perfect relief of symptoms and a small number have had second operations after a year or so, the number has been so small and the satisfaction to the women has been so great that I am satisfied to continue the purpose of sane conservation of ovarian tissue in young women. In women beyond the age of forty-five no attempt to conserve ovaries was made, unless they were unquestionably normal.

Concerning the necessity for drainage after abdominal operation, cases of this kind are fewer and fewer as years go by. Some years ago the standard practice was "when in doubt drain." Today the standard practice is, when in doubt do not drain. The best judgment is that which gives the highest standard of efficiency and the fewest doubts. In the earlier cases of this series we placed a gauze drain in a few cases for safety on account of oozing. Surely modern surgery has attained a standard of efficiency sufficiently high in the prevention of hemorrhage during pelvic surgery to secure safety without a pack. The whole question of the necessity for draining in the individual case is answered by the surgeon's success in removing all the diseased tissues giving origin to the pus. The surgeon's part in pelvic inflammatory disease is to remove the suppurating tubes and ovaries and appendix, find and close little ulcerated areas in the bowel, stop all bleeding and cover raw surfaces with good peritoneum. This done a woman who has lived long enough to get pelvic abscess is usually safe with three to five days' modern treatment for peritonitis. They seldom need rubber tubes and gauze packs after the cause has been removed. In this series there were one hundred and seventy cases of pelvic abscesses, thirty-five of which were drained; three of these patients died. All others were closed tight without drainage and all but one recovered.

CONCLUSIONS.

1. Many women acutely sick with suppurative disease of the uterus and tubes recover almost completely without surgical operation. Recovery is hastened by vigorous nonoperative treatment of peritonitis, i. e., ample quantities of morphine and other opiates; local hot or cold applications to the abdomen; absolute and continuous rest; abundance of fresh air through open windows; gastric lavage when vomiting is persistent, restriction of solid food; avoidance of cathartics and enemas; administration of large quantities of water (at least four quarts daily), preferably by mouth; normal saline solution by hypodermoclysis, in certain cases by enteroclysis, and in severe cases by all these routes combined.

2. Immediate operation is never called for; emergency operation should never be performed; every case may without danger wait for operation until at least partial subsidence of fever and pain, flattening and pacification of the acutely sick abdomen; acquisition of some degree of systemic immunity and transportation to a modern hospital; few cases need wait much longer than this; many patients may with

safety be operated upon one or two days after admission to the hospital.

3. No woman with pelvic disease need wait longer than is necessary to "get things fixed" for proper operation. The records show that reasonably early operation is preventive surgery against long preoperative and postoperative invalidism, against extension of disease to the other tube and one or both ovaries, against dense adhesions and ulceration of the bowel, and prevents the necessity of mutilating operations upon the pelvic organs, reparative operations upon the bowels, and of an unnecessary proportion of cases of drainage.

4. Systematic and thorough operative procedures are called for; all disease should be cured at one operation in approximately ninety-five per cent. of cases. Conservation of normal organs is one thing, preservation of diseased ones quite another. No normal tube or ovary should be removed; no diseased one should be preserved. Mortality is lower, convalescence smoother, and cure more complete following complete than incomplete removal of disease.

5. Abdominal drainage following removal of diseased tissue is necessary in less than twenty-five per cent. of one hundred and seventy women with pelvic abscess and in less than ten per cent. of the total number of five hundred women in this series.

6. Postoperative treatment is the same as that for peritonitis; rest, abundant quantities of morphine, normal saline solution by hypodermoclysis, water or soda solution by enteroclysis, at least four to six quarts of fresh palatable water by mouth each twenty-four hours for four or five days, hot or cold refreshing liquid food and beverages when the stomach becomes retentive, gastric lavage for bilious vomiting and the rigid avoidance of drugs, enemas, rectal tubes, solid food and other such stimulants to peristalsis until the abdomen becomes flat, and the patient passes flatus (usually from four to five days or a week depending upon the severity of the disease).

7. The mortality of suppurative disease following operation should not be more than one per cent., the stay in bed rarely longer than two weeks, there should be no excessive postoperative menstruation, no pelvic pain nor purulent discharge.

Importance of Palpation of Pelvic Ureters in the Diagnosis of Abdominal Disease*

By DAVID W. TOVEY, M.D.,
New York,

Fellow of Academy of Medicine; Adjunct Professor of Gynecology, New York Polyclinic Medical School and Hospital; Gynecologist to Harlem Dispensary, and Attending Gynecologist to Broad Street, St. Mark's and Community Hospitals.

Palpation of the female pelvic ureter is a much neglected method of diagnosis. Max Sänger in 1886 showed that the pelvic ureters could be palpated, but it is easier to palpate diseased ureters. At the New York Polyclinic I had no difficulty in teaching students how to palpate ureters, after they had learned their position by the insertion of catheters. During vaginal examinations there is nothing between the ureter and the finger but the vaginal wall (1). A thickened tender ureter palpated through the vagina frequently will give a clue to a diagnosis in cases in which a diagnosis has not been made. The lower ureter becomes thickened and enlarged in diseases of the kidney; because it takes part in the involvement in the inflammatory process, dilatation also occurs and is the result of infection. Changes in the wall of the ureter are always present whenever pyelitis exists (2).

In mechanical dilatation the ureter is thickened below and dilated above the point of obstruction. The changes in the ureteral meatus seen through the cystoscope described by Fenwick, which he affirmed afforded a clue to the nature of the disease of the kidney, are due to the changes in the lower ureter. Pain in the region of the kidney, radiating to the lower abdomen, genitals, and thighs, is typical of renal or ureteral affections but it is often absent. Abdominal pain not associated with pain in the back and without urinary symptoms is frequent. Pain due to disease of the urinary tract may be intensified in different regions of the body, the explanation of which must be sought in the nerve plexuses and anastomoses with other nerve plexuses, also in the contact of the kidney and ureter with different abdominal organs and the extension of disease from these organs.

The ureter is supplied by the aortic, renal, ovarian, superior and inferior mesenteric, hypogastric, vesical, lumbar and sacral plexuses. These plexuses, anastomose with each other and with all abdominal sympathetic plexuses, connecting the ureter through the nerve plexus with all abdominal viscera.

The anastomosis of the nerve plexuses of the ureteral and uterine plexus explains the reflex pain and bleeding due to ureteritis; anastomosis with the mesenteric plexus explains pain the the gallbladder, stomach, intestines and appendix. With the vesical plexus pain in the bladder and ureters, with ovarian pain in the ovaries, hypogastric pain in the genital tract, renal pain in the kidney, sacral pain in the rectum, pelvic pain in the thigh, and intercostal pain in the abdominal wall, lesions of the kidney and ureter may simulate every abdominal and pelvic disease from gallstones to ectopic pregnancy.

*Read at the Thirty-fourth Annual Meeting of the American Association of Obstetricians, Gynecologists, and Abdominal Surgeons, Albany, N. Y., September 19, 20 and 21, 1922.

Hunner (2) diagnosed five hundred cases of ureteral stricture in three and a half years and he concluded that it was the cause of more kidney disease than any other factor, and a frequent cause of unnecessary abdominal operations. Frequently there is no pain referred to the urinary organs, only repeated attacks of epigastric distress and at times fever. Pain may be referred to any organ in the abdomen and to any part of the abdomen.

In lithiasis the position of the stone, whether in the kidney or the ureter, has little bearing on the distribution of pain. A stone in the kidney may cause pain limited to the lower abdomen and vulva, and stone in the lower ureter produce pain in the renal region or high in the abdomen.

Braasch (4) reports that in ten per cent. of the cases operated in by Mayo for stone, there was no definite pain.

Bugbee (5) says: "It is possible to make a diagnosis with the x ray and ureteral catheter in two thirds of the cases. Out of seventy-six cases of calculi in the lower ureter not showing a shadow, twenty-two patients passed calculi.

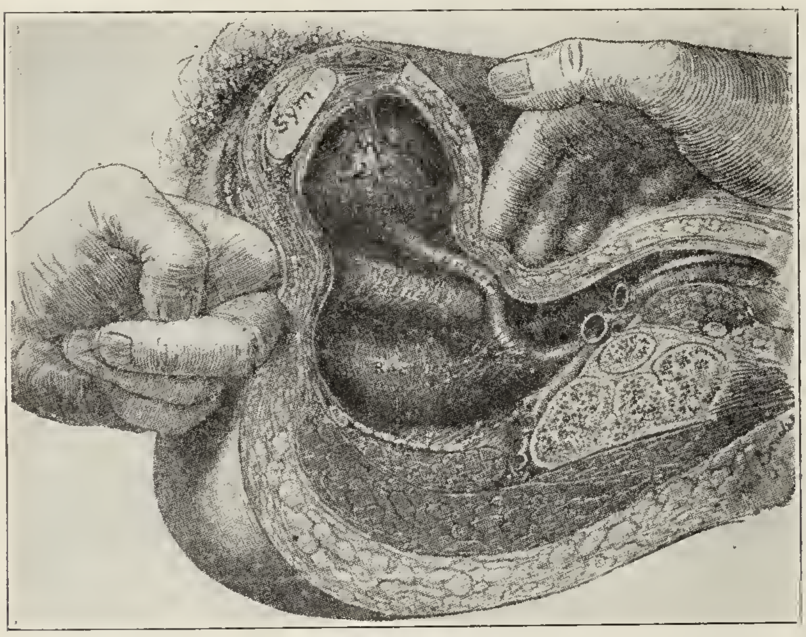

FIG. 1.—Sagittal section of the female pelvis, showing bimanual palpation of lower end of ureter.

Barney (6) reports that in eighteen per cent. of his cases of ureteral calculi, the patients had one or more previous operations and says: "These mistakes were made by skilled surgeons with every facility for arriving at a correct diagnosis." He also says: "Abdominal exploration is sometimes necessary to differentiate between lithiasis and acute conditions of the abdomen. Urine is negative in eight per cent. and the x ray in six to eleven per cent. of cases. The pelvic ureter is always thickened and palpation will give a clue to the diagnosis."

Krestschimer (7) reports that in forty-four and one half per cent. of his pyelitis cases the patients were operated upon for some abdominal condition.

Cecil (8) says that in thirty per cent. of his hydroureter and hydronephrosis cases, the patients had had abdominal operations for the relief of pain, subsequently demonstrated to have been of renal origin.

Green (9), in an article on the stricture of the ureter as an explanation of obscure abdominal conditions, says: "The diagnosis is made by urinary symptoms and by palpation revealing tender spots low down in the broad ligament."

Janes (10) says: "The terminal three inches of a pathological ureter can be felt as a tender tube along the anterior and lateral fornices of the vagina."

In tuberculosis of the kidney frequently the only symptoms present are a dull ache in the lumbar region with frequent urination.

In 1903 Bazy (11) described as diagnostic of tuberculosis of the kidney, the reflex pain on touching the ureteral meatus through the vagina.

Bugbee (12) found that in a large percentage of his tuberculous cases there was stricture, and that a thickened irregular ureter could easily be palpated through the vagina.

Ureteritis due to infections of the cervix is frequently mistaken for cystitis.

In 1886 Sänger (13) reported cases of ureteritis treated for long periods as cystitis.

In an article published in 1920 (14) I said that ureteritis due to lacerations and infections of the cervix, if treated early, will not result in stricture. Bladder symptoms following hysterectomy are frequently due to ureteritis and not to cystitis. Palpation of the pelvic ureter will give a clue to the diagnosis.

TECHNIC OF PALPATION

To palpate the ureter from the ureteral orifices at the trigone to the base of the broad ligaments, to orient the position, imagine a line from a point half an inch in front of the cervix to a point about half way between the lateral border of the cervix and the lateral pelvic wall. The fingers are introduced into the anterior lateral vault of the vagina and counterpressure is made downward through the abdominal wall. Draw the fingers forward, and as the tissues slip through the fingers the ureter is felt as a flattened cordlike body, smaller than a goose quill, displaced in its bed of loose cellular tissue. It can be rolled from side to side under the palpating fingers by moving them toward the broad ligament. Posterior to the broad ligament it is felt above the spine of the ischium covered by peritoneum, by palpating it against the pelvic wall.

Judd (15) advises sweeping the fingers above its location as in pricking a guitar, always from above downward. It may run as high as an inch above the spine of the ischium.

The normal ureter never causes pain on palpation. If diseased, it is enlarged and feels like a hard cord, sometimes as large as a lead pencil or even larger. Palpation brings an intense desire to urinate. It is easy to distinguish a diseased ureter by comparing it with its fellow which is rarely diseased, or if diseased at all, never to an equal extent.

REPORT OF CASES.

CASE I.—U. S., twenty-five years old. Temperature 104°, nausea, epigastric distress, pain and tenderness in region of the appendix. Appendectomy was advised by her physician. Examination by vagina showed the right ureter enlarged and tender. Palpation brought intense desire to urinate. Left ureter was enlarged and tender, but not as large as the right. A diagnosis of pyelitis was confirmed by examination.

CASE II.—M. H., aged thirty-two years, suffered from pain in the left ovarian region which was worse at menses. She was sent for operation. The left ureter was found to be enlarged and tender. A diagnosis of ureteritis due to stricture was confirmed by ureteropyelogram.

Case III.—S. U., reported by Dr. Wells. The patient suffered from acute pain and tenderness in the gallbladder region, with chills, fever, nausea and vomiting, and was sent for gallbladder operation. The right ureter was enlarged and tender and she passed a stone the size of a shoe button after ureteral catheterization.

Case IV.—K., the patient, had a tumor in the right side of the abdomen, which was diagnosed as enlarged gallbladder. There was frequent urination, with blood in the urine attributed to inflamed ureteral meatus. X ray was negative. Right ureter enlarged and tender. Collargol picture revealed soft stone the size of a plum in the kidney pelvis. Large pus kidney was removed with soft stone at operation.

Case V.—D., the patient, was sent to the Polyclinic Hospital by Dr. Wells with a diagnosis of ectopic pregnancy, last menstruation three months previously. She complained of severe pains in the right ovarian region, accompanied by spotting. Uterus was enlarged with a two and a half months' pregnancy, right ureter was enlarged and tender. Diagnosis, pregnancy with ureteritis and pyelitis.

Case VI.—F. S., the patient, twenty-nine years old, was sent with a diagnosis of ectopic pregnancy; last menses two and a half months ago, irregular bleeding with attacks of severe pain in right ovarian region, nausea and fainting. She said the pain felt as if it was in a tube like a banana in her pelvis. Examination revealed a uterus enlarged, softened, the size of a two and a half months' pregnancy. In the left cornu was a hard mass the size of a plum, and a bloody discharge of brownish color from the vagina. The right ureter was enlarged, very tender, and palpation gave intense desire to urinate. There was a cramplike pain in the abdomen with nausea and faintness. Diagnosis, two and a half months' pregnancy in left cornu; ureteritis due to stone.

Case VII.—D. S., aged sixty years, referred with a large kidneyshaped mass on the left side below the ribs extending into the kidney region. Palpation revealed a normal ureter. Ureteropyelogram showed a normal ureter and kidney pelvis. A large sarcomatous spleen was removed at operation.

Case VIII.—J. U., aged thirty-five years. Since the birth of a child three years ago the patient had suffered from indigestion, pain in right abdomen, and frequent painful urination. She had been treated for cystitis, and advised to have appendix and ovary removed. Examination showed the cervix lacerated, eroded, and infected, right ureter enlarged and tender. Diagnosis, ureteritis and cervicitis.

Case IX.—M. P., aged thirty-five years, suffered from an attack of severe pain referred to the right iliac region, with nausea, epigastric distress, and frequent and painful urination. Her physician thought he felt an enlarged appendix. The right ureter was enlarged to the size of a finger, and very tender. Diagnosis, tuberculosis of kidney confirmed. The enlarged appendix her physician felt was a tuberculous ureter.

Case X.—J. R., aged twenty-five years, complained of pain on the right side, indigestion, constipation, and epigastric distress. Appendix, Lane's kink, and right ovary were removed without relief. X ray and urine were negative. Palpation revealed a hard tender mass in the right lower ureter, pressure on which brought intense desire to urinate. Diagnosis of stone in lower ureter was confirmed by examinations.

The author's references will appear in his reprints.

The Significance of Inflammatory Ureteral Stricture in the Female*

By THOMAS H. CHERRY, M.D., F.A.C.S.,
New York,
Visiting Gynecologist to Harlem Hospital; Associate Professor of Gynecologist at the Post-Graduate Hospital.

Hunner, in 1916, in a report of fifty cases of ureteral stricture, called the attention of the medical profession to the frequency of this condition in the female. Subsequently, other American observers have from time to time reported instances of this urinary disorder. European urologists, while recognizing the pathological entity, in definite renal infections showing evidences of ureteral obstruction, do not lay much stress upon the nonobstructive type of ureteral stricture.

Gynecologists, without a doubt, are consulted by female patients suffering from urinary tract infections more often than the urologist. Fully half of my own gynecological patients complain of urinary symptoms of varying degrees. It, therefore, seems advisable for one specializing in diseases of women to investigate the urinary tract by the approved methods of cystoscopy and ureteral catheterization. Urinary symptoms may occur from pathological conditions in the kidney, ureter, and bladder. Furthermore, they quite often have their origin outside the urinary tract, and are produced by pathological conditions of the uterus, tubes and ovaries, either from pressure or by distortion of the bladder from inflammatory adhesions.

ANATOMY OF THE URETER

The ureter is a musculofibrous tube connecting the kidney with the bladder; it averages about thirty cm. in length, beginning at the pelvis of the kidney at the level of the second lumbar vertebra, and runs downward parallel to the vertebral column behind the parietal peritoneum, to the brim of the pelvis where it is crossed by the ovarian vessels. It now crosses the common iliac vessels, dips into the true pelvic cavity, enters the broad ligament which it traverses in a downward and inward direction, passes under the uterine vessels, and enters the base of the bladder. In its course through the broad ligament the ureter is closely adherent to the posterior layer.

---

*Presented before the West Side Clinical Society, October 12, 1922.

The ureter is composed of three coats; mucous, muscular, and fibrous. The mucous membrane consists of transitional epithelial cells of several layers continuous with that of the renal pelvis and bladder. The muscular coat consists of an inner longitudinal and an outer circular coat; it is of the unstriated involuntary type of muscular tissue, and has the function of peristaltic action. The fibrous sheath is composed of a fibrocellular substance that surrounds the ureter and is of especial importance because it gives support and contains the bloodvessels that nourish the ureter.

CLASSIFICATION

Two general groups of ureteral stricture can be made; first, obstructive stricture; second, nonobstructive stricture.

OBSTRUCTIVE STRICTURE.

Obstructive stricture can be defined as an infiltration of the ureter that encroaches upon the lumen in such a manner that dilatation of the proximal ureter and renal pelvis takes place.

Etiology—This type of stricture is frequently produced by primary infections in the kidney of hematogenous origin. Infected urine from the renal focus in its passage downward may set up an inflammatory area in the ureter, or a direct extension through the lymphatic channels may take place from the kidney to the ureter, so producing a secondary inflammatory reaction in that structure. A good example of this type of infection is that of tuberculosis. Other renal infections due to pyogenic organisms may also produce such lesions.

Pathology—Under these circumstances there always occur a hydroureter and hydronephrosis of varying extent, and in some cases pyonephrosis, with impairment of renal function.

Symptoms—These patients practically always have symptoms referable to the urinary tract that are predominant factors. They complain of pyuria, dysuria, hematuria, and abdominal pain. Objectively there are evidences of pyuria and cystitis, and definite signs of renal infection. Cystoscopic examination shows a secondary bladder infection of varying degrees of intensity; the ureters may offer an impassable stricture, or they may allow passage of a small ureteral catheter or bougie. Urine from the infected side shows numerous pus cells and on culture may show the type of bacteria producing the condition. The phenolsulphonephthalein and indigocarmine tests as a rule show an impairment of renal function. In cases of long standing the blood chemistry should be investigated to ascertain the degree of nitrogen retention present. Pyelography is also a great aid in making an accurate diagnosis and to locate definitely the point of stricture.

Treatment—This is clearly defined. When a diagnosis of renal tuberculosis has been made, a nephrectomy is indicated. When other bacteria cause the trouble and in cases where the renal infection is not so advanced that there is serious impairment of function, ureteral dilatation and renal lavage should be instituted, for by the establishment of proper drainage it is truly surprising what improvement will take place. In many instances a cure can be accomplished. Improvement is shown by the lessening of the pyuria and dysuria; decrease of vesical symptoms, and the improvement of renal function. The administration internally of urotropin and acid sodium phosphate is a valuable adjunct in combating this condition.

NONOBSTRUCTIVE STRICTURE.

It is this type of stricture that I particularly wish to emphasize as more difficult of diagnosis and, in consequence, more frequently overlooked. It can be defined as a small area of infiltration in the ureteral wall encroaching upon the lumen but not sufficient to produce a dilatation of the proximal portion of the ureter and renal pelvis. Their location in the female nearly always is in the pelvic portion of the ureter.

Etiology—As a rule, this type of stricture is produced by infections of the adnexa, parametrium, uterus, and cervix transmitted through the lymphatic vessels that communicate with the periureteral lymphatics. The infection so transmitted to the ureter is of a chronic low grade type, and the ureteral infiltration produced is not acute in character but insidious in its establishment.

The lymphatics of the ureter, according to Eisendrath, are divided into three sets; first, the submucous group that run under the mucous membrane and are continuous with those of the bladder and kidney; second, the muscular group that run upward from the bladder musculature through the muscular coats of the ureter; third, the external or periureteral group that are contained in the sheath of the ureter. These groups of lymphatic vessels traverse upward to the kidney substance and no doubt communicate with each other in their course. Kumita has shown that the periureteral group of lymph vessels communicate freely with the ovaries, fallopian tubes, broad ligaments and uterus. Sturmdorf has also shown that the cervical lymphatics travel upward into the myometrium of the uterus, as well as the broad ligament. It is, therefore, highly probable that infections of the endocervix, adnexa, and uterus are transmitted through the communication with the periureteral group of lymph vessels and secondarily infect the kidney and ureters.

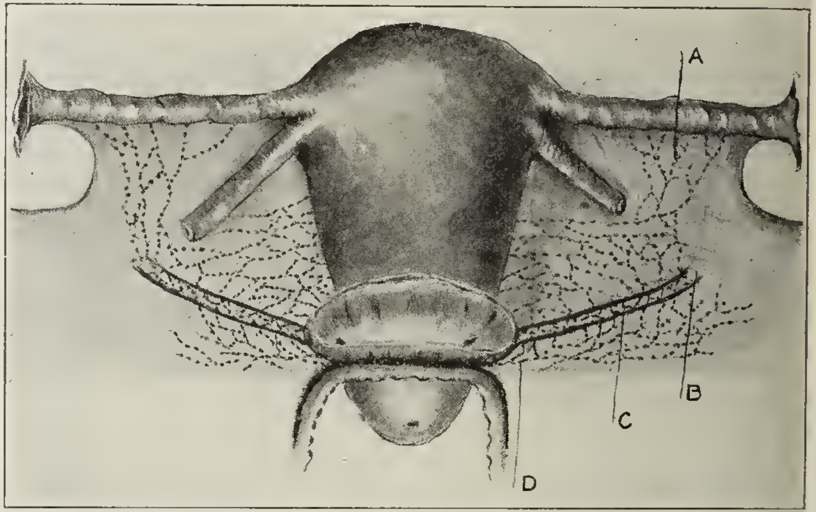

Fig. 1.—Schematic drawing showing uterus, broad ligaments, base of bladder and ureters, with the lymphatics draining the uterus, adnexa and cervix communicating with the periureteral lymphatics. A, tubal lymphatics; B, ureter; C, periureteral lymphatics; D, lymphatics from cervix.

Through the anastamosing lymphatic channels draining the cervix and adnexa with the periureteral lymphatics into the broad ligament, areas of infection in the sheath of the pelvic portion of the ureter may occur. These areas may persist and remain local

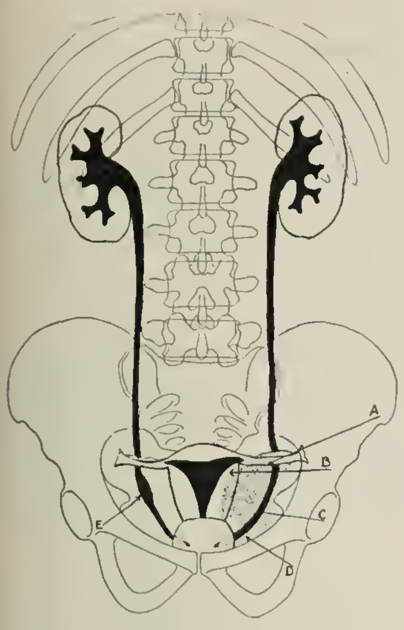

FIG. 2.

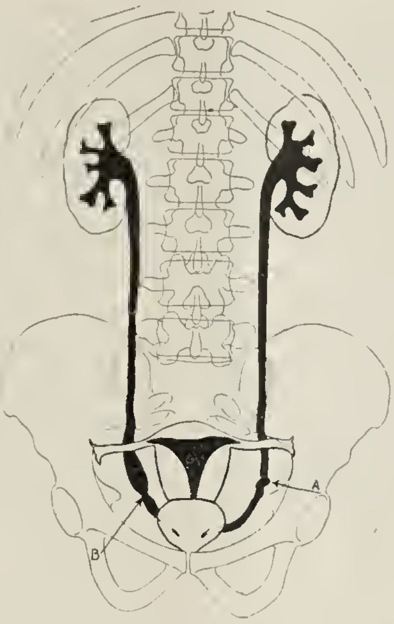

FIG. 3.

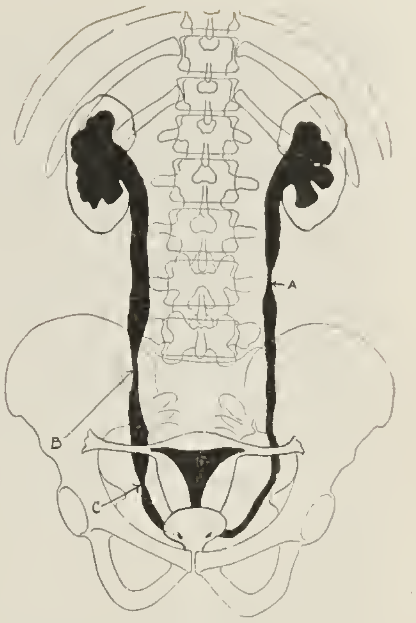

FIG. 4.

FIG. 2.—Shows on the left side a pyelographic tracing of a normal ureter and renal pelvis. In the pelvic portion of the ureter the lymph channels from the adnexa, uterus and cervix are communicating with the periureteral group. On the right side a periureteral infiltration of the right ureteral sheath is shown, a condition following operation on the cervix for endocervicitis. Symptoms of frequency and dysuria are relieved by bougie dilatation. A, adnexal lymphatics; B, uterine lymphatics; C, periureteral lymphatics; D, lymphatic vessels draining cervix; E, infiltration of ureteral sheath.

FIG. 3.—Left side shows ureterographic tracing of ureter distortion from infection of ureteral sheath with adhesions. Symptoms of dysuria, left sided abdominal pain, frequency of urination. Right side represents a ureteropyelographic tracing showing a stricture of pelvic ureter with fusiform dilatation; no obstruction present. This can readily progress to the obstructive type of stricture. A, ureteral kink; B, nonobstructive stricture.

FIG. 4.—Left side shows a ureteropyelographic tracing of an obstructive stricture of the lumbar ureter with accompanying degree of moderate hydronephrosis; diminished function of kidney. Relieved partially by bougie dilatation. Right side represents a double stricture with hydronephrosis and renal infections, with markedly diminished renal function. Bougie dilatation relieves partially. A, obstructive stricture; B and C, double stricture with hydronephrosis and renal infection.

in this part of the ureter or the infection may be carried up through the periureteral lymphatics and infect the kidney. When the infiltration remains local there forms either a nonobstructive stricture—producing urinary symptoms—or the infiltration does not encroach upon the lumen of the ureter but remains as a ureteral sheath exudate or infiltration, which produces symptoms similar to the stricture formation. This theory has been exemplified and in my opinion proved to exist in numerous cases in which the patients have been operated upon for infected endocervicitis and in chronic adnexal disease. In some instances acute infection of the kidney has occurred with a definite temperature and pyuria which, upon cystoscopic examination, has been definitely shown. This infection of the kidney usually occurs in five to ten days postoperative while the patient is still in the hospital.

The ureteral sheath lesion is a more chronic process and requires a longer period of time for its formation and the production of symptoms; there is no attendant rise in temperature and its occurrence in all cases seen by me, follows the patient's discharge from the hospital. The patient returns to the follow-up clinic complaining of frequency of urination and, upon cystoscopic examination, catheterized urine and the bladder picture are negative. Catheterization of the ureter upon the painful side does not, as a rule, show any obstruction; neither does the urine from the kidney show any departure from normal. Vaginal examination discloses a tender spot in the broad ligament in the region of the ureter. The passage of the urinary catheter in the routine examination (a No. 5, or a No. 6) as a rule relieves the patient, particularly from dysuria and frequency of urination. Acting upon these findings, it has been my routine practice, when in these postoperative cases the patients return with symptoms of this kind, to assume that a periureteral infiltration has occurred and dilate the ureter on the affected side with a No. 8, 9 or 10 bougie. Following this treatment there has been marked relief of the symptoms and in the course of time, upon repeating this line of treatment, a complete cure in the majority of cases has been obtained.

Pathology—The wall of the ureter first becomes infiltrated by round cells; later a formation of new interstitial tissue takes place that in the more advanced state may become fibrous. This process in the wall of the ureter interferes with the normal peristaltic ureteric waves. Such an interference with this function causes a loss of muscular tone followed by stasis of the urinary flow. Spasmodic contractions may also be established that are transmitted to the bladder wall producing painful contractions. Dilatation of the proximal ureter may also occur, depending upon the amount of encroachment of its lumen. This type of stricture may remain for a long period of time as a nonobstructive type but it may progress into the obstructive type, later producing hydroureter and hydronephrosis.

Symptoms—The subjective symptoms that stand out most prominently in this nonobstructive stricture are painful and frequent urination. Abdominal pain is a frequent symptom; it is usually intermittent and spasmodic in character and at times may be so acute as to influence one to operate—an urgent abdominal condition. Reflex gastric and intestinal pains occasionally are present that mask the real pathology.

Examination—There may be a tender point on the abdomen in the region of the brim of the pelvis. Vaginal investigation shows signs of endocervicitis with tenderness of the broad ligament on the affected side. Catheterized bladder urine is usually clear and microscopically negative.

Cystoscopic examination—Through the cystoscope a normal bladder mucosa and ureteral orifices are seen. Upon passing a catheter an obstruction may be met which prevents its progress, but upon manipulation and relaxation of spasm at that point it may pass readily up to the renal pelvis. In order to pass the obstruction in some instances it may be necessary to withdraw the catheter and pass a smaller one. Urine from that kidney shows nothing significant microscopically or by culture, and renal functional tests show a normal output of dye.

Pyelography—Pyelography may be of great value in this group of partial obstruction where there is some degree of ureteral dilatation above the stricture. In cases where there is no obstruction it is of little use as a diagnostic measure. It has seemed to me that the most pronounced cases of dysuria and frequency with nocturia eight to twelve times showed nothing in a ureterogram or pyelogram. In the investigation of such cases in which the urinary and genital tract appear normal, but the symptoms are entirely urinary, it has been my custom to institute immediate ureteral dilatation. When such instrumentation has produced relief of the symptoms I have diagnosed the condition as a nonobstructive stricture. This measure I have designated a therapeutic and diagnostic ureteral dilatation.

In the diagnosis of these small nonobstructive strictures Hunner uses a series of wax tipped bougies of various sizes which he introduces through a Kelly endoscope. Upon withdrawing the bougie, if he gets the socalled ureteral hang or jump, the diagnosis is correct from a clinical point of view. This method of course cannot be used satisfactorily with the water cystoscope.

Treatment—Gradual dilatation of the stricture by means of gradual bougies is the method of choice. This must necessarily continue over a long period of time, at first given seven to twelve days apart, depending upon the amount of reaction that follows. The interval is then prolonged unless the symptoms recur. During bougie dilatation over a prolonged period one must use the utmost precaution in regard to asepsis, as it occasionally happens such frequent instrumentation will set up a cystitis. To prevent such an occurrence it is a good plan to inject fifteen per cent. argyrol solution into the bladder following each instrumentation.

SUMMARY

1. Ureteral stricture in the female, of the nonobstructive type, is a much more frequent entity than is generally recognized. In view of this frequency we should investigate thoroughly the urinary tract of gynecological patients who complain of urinary symptoms.
2. The etiology of this condition is a transmission of a low grade infection through the medium of the periureteral lymphatics communicating with those of the adnexa, uterus, broad ligament and endocervix.
3. Gradual bougie dilatation is the treatment of choice and good results can be expected in the nonobstructive type.
4. In the obstructive type of stricture, with marked kidney infection and poor renal function, ureteral dilatation should be given a trial before more radical measures are instituted.

Nasal Dysmenorrhea

By A. L. LEVY, M.D.,
Jamaica, N. Y.

The following seems to be a true case of nasal dysmenorrhea.

Case I.—J. S., aged twenty-one, single, by occupation a typist, had had the usual diseases of childhood. Menstruation began at thirteen, was of the twenty-eight day variety, and usually lasted five to six days. She had always had some menstrual, but no premenstrual pain. Her history was otherwise negative, except for a submucous resection of the nasal septum seven years ago. Her last menstrual period had occurred the latter part of September, 1922.

I was called to see the patient on October 25th, three days after her regular period began, and found her in great pain. By questioning the patient I learned that her period had begun at the expected time and was accompanied by the usual pains. With this period, however, the pains increased in severity, and with the progress of the flow they became so severe as to cause retching and vomiting with the severe uterine contractions. The patient ascribed her condition to some food she had taken two days before, and thought she had an "upset stomach"; hence had not eaten anything for two days.

Examination revealed a fairly well nourished girl, menstruating, evidently in great pain, crying out with each uterine contraction. Her temperature was 99°, pulse 84, respirations 20. The heart and lungs were negative, the abdomen was soft, and there was no tenderness, distention, or rigidity. She complained of some soreness in the abdominal muscles, evidently caused by the repeated retching. The uterine bleeding was moderate in amount, and normal in appearance and odor. I was compelled to administer a hypodermic injection of morphine to control the pain, and advised hot applications to the lower abdomen, hot drinks, and an enema to clear the bowels. I also prescribed tablets of phenacetine and codeine, and left, feeling that in a short time the pains would cease.

About six hours later I was called again, and found the patient in greater agony than before. Examination was negative. I had to repeat the morphine, ordered more hot drinks, another hot enema, and a uterine sedative, and went away.

Two hours later, I was notified that the patient was in very severe pain and had vomited several times. When I got there, she was tossing about on the bed, suffering from excruciating pain. Examination again showed no new evidences of any pathological condition other than that found at the previous visits, except a slightly increased pulse rate. I was about to administer another dose of morphine, when I thought of an intranasal application of cocaine. To control the experiment, and guard against suggestion as a possible factor, I first applied plain water to both lower turbinates and the portion of the septum opposite these. Ten minutes of waiting brought no cessation of the pains; so I painted the same areas with twenty per cent. watery solution of cocaine. Five minutes after this application, the pains stopped and the patient was comfortable.

I saw her again the following day, and found her up and about, free from pain except for a slightly sore abdomen. She had had no further colic after the intranasal application of cocaine. I finally advised the patient to have these intranasal genital spots cauterized, feeling convinced that this was a true case of nasal dysmenorrhea.

The Differential Count of Appendicitis, Tuboovarian Diseases and Infection of the Uterine Cavity

By A. J. HINKELMAN,
Oklahoma City, Oklahoma.

Diagnosis of infection of one or the other of these three different parts of the female anatomy is a question with which the surgeon and the gynecologist is frequently confronted. The results, however, of the best technic of modern means of differential counting from stained films of blood made on slides have always lacked the accuracy and consistency to apply safely to anything, except gross or marked variations of the normal numerical relationship of the various white cells of the blood, and, consequently, never have been of much value in differential diagnosis of internal infections.

Hematimetric differential counting (1), however, or counting from a measured quantity of blood on the counting chamber, and based upon a count of from three thousand to eight thousand cells, has revealed to me that the character of the differential count is very consistent in the various infections commonly met with in surgery and gynecology, and furthermore, that there is a distinct difference in the character of those infections that readily threaten the life of the patient and those that do not. The following tables, which constitute a representative average of a large number of differential counts made, show how this difference is manifested in the infections of the three principal seats dealt with in this article.

In the case of appendicitis it will be noted that there is a definite inverse manner in which the process affects the two types of granular cells of the blood, the polymorphonuclear cells and the eosinophiles. Regardless of whether the process is acute, subacute, chronic or the appendix ruptured, the former cells will always be found above normal absolute numbers, while the latter will be found much reduced and usually absent among from three thousand to eight thousand cells. The same is also true to some extent regarding the small lymphocytes. There is always a tendency of these cells to be below normal numbers rather than above, depending upon the severity and duration of the infection.

The count of tuboovarian infection is more or less of the opposite character. In all such cases, where there is an increase in the total number of leucocytes, this increase represents to some extent all of the cells commonly present in the blood except the large lymphocytes, which usually remain normal in numbers.

On the other hand, again, the count of uterine infections, such as that following incomplete abortion, is much the same as that of acute appendicitis, different only in the respect that the reduction of the number of eosinophiles and small lymphocytes is of a more striking character.

CONCLUSION.

According to the foregoing, it is plain that the process of chemotaxis is differently evolved in the usual infections of the three different seats herein dealt with.

1. In the case of appendicitis it is apparent that the positive chemotactic elements, liberated into the circulation from the inflamed area, are solely those that stimulate the production of the polymorphonuclear type of leucocytes. As a result of this, the eosinophiles are taken out of the circulation more rapidly than they are replaced, resulting in a rapid reduction of their usual absolute numbers, while the same reduction is also shown sooner or later regarding the small lymphocytes. In brief, it can be said that the count of an uncomplicated case of appendicitis is that of a polymorphonuclear leucocytosis, with a marked reduction of the absolute number of eosinophiles and a tendency toward a reduction of the normal number of small lymphocytes.

2. The differential count of tuboovarian infections differs from appendicitis in the sense that the chemotactic elements liberated from tuboovarian infections stimulate, to a greater or less extent, the production of all of the leucocytes commonly present in the blood, excepting the large lymphocytes. The count is distinctly that of an absolute leucocytosis, whenever there is an increase, with the tendency of both the eosinophiles and the small lymphocytes to rise considerably above normal absolute numbers.

3. In the infections of the uterine cavity, the chemotactic elements liberated are apparently of the same character as those from the inflamed area of an acutely diseased appendix, only of a more powerful nature, or liberated in greater quantity, resulting in a characteristic polymorphonuclear leucocytosis, with a striking reduction of the absolute number of eosinophiles and the small lymphocytes early in the process.

Complete Congenital Absence of the Vagina, Associated with Bilateral Hernias of Uterus, Tubes and Ovaries*

By D. DEUTSCHMAN, M.D.,
New York.

Case I.—Mrs. E. A., thirty-four years of age, was born in Russia, a housewife by occupation. No genital defects were present, as far as could be ascertained, in any member of her near or remote relatives. The patient had never menstruated, nor had there been any vicarious discharge of blood from any organ, and never had had any periodical pains or uneasiness in the pelvic region. Mentally she was bright, alert, and in appearance was typically feminine.

At the age of eighteen years, on the advice of her relatives, she consulted a physician in her native town concerning her delayed menstruation. The doctor (?), without subjecting the virgin to the indignity of a pelvic examination, pronounced the case as one of an abnormally thick, imperforate hymen and advised the patient to marry, advice which she readily acted upon. This therapeutic suggestion, however, was ineffectual and so the matrimonial bliss was of short duration, terminating after several futile attempts at intromission.

About six months preceding her operation the patient began to complain of bilateral inguinal pain, which became intensified on overexertion. Physical examination showed a young woman with typically feminine features. The mammary glands were normally developed and the pubic hair was of normal feminine distribution. The mons veneris and the external genitalia were regular in character. At the usual site of the hymen there was a cord septum and in place of the vulvar orifice there was the meatus urethræ, which was somewhat dilated and which was demonstrated by the insertion of a catheter through this opening into the bladder. A rectal examination revealed the absence of the vagina, showing the vesical and rectal walls in contact, and the catheter which was inserted into the bladder could easily be felt through the rectum. No uterus, tubes, or ovaries could be made out. There was no sign of any collection of menstrual fluid in the pelvic cavity. In the right inguinal region was a mass which, after coughing, assumed the size of a pigeon's egg. It apparently emerged from the external inguinal ring and was completely reducible. In the left inguinal region there was a similar mass but smaller in size.

---

*This case was presented before the Bronx County Medical Society, October, 1922.

On October 20, 1922, the patient was operated upon for bilateral hernias. The following condition was revealed. On opening the sac on the right side it was found to contain a large cystic ovary, which was adherent with its ligament to the sac. A mass was felt in the anterior wall of the sac. This was recognized to be a rudimentary uterus and tube. The posterior wall of the uterus formed the anterior wall of the sac. The uterus was, therefore, extraperitoneal; in other words, it was a sliding hernia. This, of course, made it impossible to reduce the uterus and at the same time perform a high ligation of the sac. The peritoneum was, therefore, peeled off from the posterior wall of the uterus and the sac then ligated at its neck. That left the uterus, tube, and ovary lying free in the inguinal canal.

Since the uterus and tube were worthless and the ovary cystic they were all removed. On the left side a sliding hernia of the left tube and ovary was found. Since this ovary was also cystic it was thought best to extirpate it. The excised uterus had no lumen and to its right cornu was attached a short rudimentary tube. This also had no lumen and no fimbriæ. The right ovary was normal in size but full of cysts. The left tube was similar and cordlike and also without a lumen. The left ovary was also cystic.

The explanation offered in the medical literature regarding the disturbing factor in the embryonic cells leading to congenital anomalies of the genital organs has always been of a speculative character. It is assumed that failure in the development of the Müller ducts will result in some genital deformity, but the primary or underlying cause of this embryological perversion is still shrouded in a mystery.

CONCLUSION.

The congenital anomaly in this case is, apparently, due to a failure of the Müller ducts to develop properly. The lack of fusion of the lower extremities of these ducts resulted in the absence of the vagina. The uterus was formed from the right duct or from a short fused section of both ducts. Its development was interfered with and no lumen was formed in the uterus. The tubes that were removed were strands of the upper ends of the Müller ducts.

The presence of the pelvic organs in the inguinal hernias is interesting. Normally the ovary descends from a position in the lumbar region, which it occupies in the eighth week, to the final position in the true pelvis. Its downward descent may result in its halting at any level, a process similar to that of the testes. What happened in this case was a descent of the ovary to the inguinal canal. On the right side this descent dragged along the rudimentary tube and uterus and, on the left side, the rudimentary tube.

The patient made an uneventful recovery and almost a year after the operation had not shown any effects of the double ovariectomy.

In connection with this case I wish to express my gratefulness to Dr. Eugene Klein for his valuable assistance at the operation and for his cooperation in the preparation of this case report.

1801 Crotona Avenue.

Report of a Case of Postmortem Cæsarean Section

By M. J. STONE, M.D.,
New York.

HISTORICAL.

There are four fairly distinct periods during which postmortem Cæsarean section was practised with more or less regularity. The first period dates from Cæsar's birth to the sixteenth century, the second from the sixteenth to the eighteenth century, the third from the eighteenth to the nineteenth century, and the fourth from the nineteenth century to the present day.

Even before Cæsar's birth, legend has it that Æsculapius, god of medicine, was delivered by Cæsarean section and Bacchus, god of wine, was delivered by Mercury in a similar manner. Also included in the list are Lycus, Manilius and Scipio the African. The Cæsarean operation early in its practice enjoyed much favor by benefit of civil laws and ecclesiastical mandate and encouragement.

However, during the eighteenth century it was brought into disrepute because of the common practice of operating on women before death. Tarnier, himself, while still an intern suffered public condemnation, his accusers asserting that he performed the operation antemortem, upon a woman dying from meningitis and was required to offer explanations, and clear himself from blame. It was he who first suggested that postmortem Cæsarean section had better not be performed before the viable period of gestation, which he placed at seven and one half months.

During the eighteenth century as Cæsarean section fell into disrepute, accouchement forcé gained in favor and was looked upon as the operation of choice. However, about this same time Cæsarean operations upon the living were being performed in increasing numbers with a fair degree of success by Tarnier and others, and the mortality rate lessened as improvements in technic were evolved. Reflected glory began to shine upon the one time honored postmortem operation so that about the latter part of the nineteenth century, Cæsarean section upon the dead was again favorably accepted (1).

REPORT OF CASE.

Case.—The patient, Mrs. I. W., thirty-eight years of age, para IX, in the eighth month of gestation was admitted to Lebanon Hospital on January 6, 1922, suffering from bronchopneumonia and pulmonary edema. Her temperature was 102° F., pulse 120, respiration 45. Dyspnea, cyanosis, edema of lower extremities, and enlarged liver were outstanding evidences that her rheumatic heart, dilated to right and left, weakened by former pregnancies, groaning under the load of the present one, and overwhelmed by the superimposed acute infection, would no longer hold out against such tremendous odds and death was imminent. Measures for removing the child at this time were deemed inadvisable on account of the critical state of the mother. An immediate venesection, removing 600 c. c. of blood, large doses of atropine, the administration of digitalis, and other supportive and stimulative measures prolonged life until seventy-two hours after admission to the hospital. Death being verified by another physician, I removed the child exactly one minute later by Cæsarean section. All necessary instruments for removal and resuscitation of the baby had been held in readiness constantly at the patient's bedside. Spontaneous respiration did not occur, but after vigorous efforts at resuscitation the child began to breathe rhythmically thirty minutes after delivery. It took feedings very well through a dropper, cried lustily, maintained a healthy pink color, and gave every indication that it might survive. However, fifteen hours later it became cyanotic, breathed with difficulty, and promptly died.

LEGAL ASPECT.

If consent for operation is not given promptly, or is even refused, and the fetal heart is still beating, it is not only permissible but imperative that the physician immediately do everything in his power to save the child (2). However, it is advisable, whenever possible, to have another physician verify the death to save oneself from unpleasant criticism.

THE PROGNOSIS.

As regards the survival of the child, prognosis depends upon the following considerations which are discussed below:

1. Month of gestation.
2. Cause of death of mother.
3. Time elapsed between death of mother and extraction of child.
4. Weight of child.
5. Syphilis or tuberculosis acting as cause of death or concomitant condition.

Postmortem Cæsarean section should not be attempted before the thirtieth week of gestation.

The child has a good chance to live if death of mother has been sudden, either traumatic or organic, such as embolism, etc.

The outlook for the child is poor if the mother has died after a prolonged illness, especially from pulmonary or cardiac disease, in which case there has occurred a carbon dioxide stasis and the oxygen which should go to the infant is held by the mother.

Blood diseases, severe acute infections, and poisoning give a bad prognosis. In the latter two conditions placental apoplexy has been found.

It is futile to attempt to obtain a living child more than twenty-five minutes postmortem.

The best results are obtained within the first seven minutes, after which time the child's chances for survival are markedly diminished.

The weight of the child and whether or not syphilis or tuberculosis is present are factors which affect the life of the child in much the same way as in delivery during life.

A New Type of Cæsarean Technic

By ALBERT M. JUDD, M.D., F.A.C.S.,
Brooklyn, N. Y.,

Senior Attending Obstetrician and Gynecologist to the Kings County Hospital; Consulting Gynecologist to the Swedish, Jewish and St. Joseph's (Far Rockaway) Hospitals; Gynecologist to the Long Island College Hospital, etc.

The history of Cæsarean section is clouded in obscurity. Many statements, illogical and beyond proof, have been made regarding the efforts of the early obstetrical surgeons. Efforts made to discover traces of its origin in the Talmud have been refuted by equally enthusiastic writers and searchers after truth. "Numa's law," established by Numa Pompilius about 700 B. C., interdicted the interment of a woman, big with child, until her belly was opened. This wise and prudent law was received and adopted throughout Christendom.

From a review of contemporary literature, we conclude that the earlier efforts to save the unborn child were confined to postmortem procedures and were then gradually extended to an attempt to save both mother and child. These efforts were, of course, discouraging up to the advent of antiseptic and aseptic surgery. During this time, dating from the fifteenth century to the time of Lister, the movement had its periods of rise and fall, according to the thinking and acting men of the time in the art of obstetrics. As has been the case with all movements, the development of Cæsarean section to its present status has been a long and difficult task, accompanied by tragedy, and unfortunately tragedy still lurks in the shadows of this important procedure.

All of us who operate to any extent have had unfortunate results. We have all seen classical cases of Cæsarean section, socalled elective cases in which the patients, who never had had a vaginal examination, died from peritonitis. This is a rare occurrence, of course, but it happens sufficiently often to make us stop and think before suggesting the operation. Many of us can remember when the operation was a widely advertised feature of our clinics, which were always well attended, and the operating room amphitheatres crowded to full capacity. The technic of this operation has varied from the classical procedure of hysterotomy to the Porro method; the kind of incision has also changed, as well as the methods of closure of the uterine wound.

Deaths of mothers from peritonitis and other infections have followed what has been considered greater conservatism in the use of other methods of delivery, necessitating, often, the sacrifice of the child as well. It is the failure to realize the immediate dangers from infection and the invalidism resulting from injuries to the birth canal that is frequently the deciding factor against abdominal interference. These unfortunate incidents have led to the conclusion that in those cases in which the patient is either potentially or frankly infected, we must abandon the classical procedure and attempt to avoid the probabilities or possibilities of infection by an extraperitonealization of our operative field. There are real extraperitoneal operative procedures.

The history of the operative methods of delivery shows numerous revivals at different periods of a procedure which had been carried out years previously, but, so far as I can find, no mention is made of the method I advise here. As far back as 1870 the extraperitoneal method of delivery was revived by T. Gaillard Thomas, to which he applied the term gastroelytrotomy. In the third edition of De Lee's book (1) he states his choice of cases in which the classical operation should be performed and adds: "In all other clean cases Krönig's method is the one of choice. When the woman is positively infected, when she has had many attempts at delivery, if a Porro is not done, the author holds that craniotomy is the safer operation." He further states: "In those cases where infection is apparently mild, or only suspected, the true extraperitoneal operation of Latzko is the one to be selected."

I also quote B. C. Hirst (2). He argues in favor of the extraperitoneal operation even in clean cases: "If a patient comes to me not merely suspicious but indubitably infected, I prefer the operation I have done with success in several instances, that is, the delivery of the uterus through a long abdominal incision; scrupulously careful padding off; the evacuation of the womb, its supravaginal amputation, etc." All these efforts, with the exception of the Latzko extraperitoneal procedure, vary only in degree from the original Porro, but all are preceded by delivery before hysterectomy. The only recent real work of the Latzko type of operation has been carried out by Asa B. Davis.

Much energy has been expended in an attempt to prove to the medical public that a transperitoneal operation could be made extraperitoneal. The arguments are, to my mind, illogical and unconvincing. By statistics you can prove anything, because human judgment is faulty. We never know when a patient becomes actually infected, consequently, when one of these potentially infected patients recovers after a transperitoneal flap procedure, we pat ourselves on the back and say: "Another victory over King Streptococcus," when, as a matter of fact, those of us who have been operating for over a quarter of a century could cite innumerable recoveries following the old classical hysterotomy in the same type of cases. The arguments may well be classed as camouflage. I do not decry the arguments or the efforts, only the results. When we see a patient with ruptured membranes, who has had numerous vaginal examinations, with perhaps an attempt at delivery by forceps, who has a temperature and a rapid pulse, and has already shown the preliminary signs of sepsis, we are dealing with a uterus which has become as dangerous to the organism as an inflammatory appendix. When once you make such a diagnosis, it must be dealt with accordingly. This has been attempted in the past, as the history of the development of the operation shows, but in a reverse order, namely, hysterotomy succeeded by hysterectomy.

Why all this prologue? Am I to tear down and not try to build up? No! I have a procedure to offer, well knowing the criticisms and storms of disapproval it will bring upon my head.

In the first place, having decided we have a frankly infected uterus, why make any attempt to bury it in the rich lymphatic plexus of the pelvis? If it is really an infected case we cannot bury it deep enough to avoid the next step in the history of the case, namely, peritonitis and death, because the peritoneum is part of the lymphatic system. *It must be removed.* Here is where even Porro himself failed because at the time during which he lived, other operators made the same mistake. What is this mistake? Hysterotomy preceding hysterectomy—a simple transition of the order of procedure is all that is necessary, i. e., *Hysterectomy preceding hysterotomy.*

The operation requires, of course, an extensive abdominal incision, sufficient to eventrate the uterus with its contents. The next step is a careful packing off, by means of wet gauze, of that portion of the pelvic and abdominal cavity posterior to and above the uterus, not only to prevent trouble from extrusion of the intestines, but also to catch any possible spill from the amputation, through the cervix. This is minimal, because of the fact that in the cases selected for this procedure, the membranes have already ruptured and the amniotic fluid has drained away. The hysterectomy is done by preceding the excision by the clamp method for the control of hemorrhage; a stripping downward and packing off of the bladder; then a quick cutting of the broad ligaments and the cervix with scissors. The time, from the shutting off of the circulation to the passing over of the hysterectomatized uterus to an assistant for incision and delivery, should not exceed five minutes. This is ample time for the delivery of a living baby. I have had only one postmortem Cæsarean section and the interval, in that particular case, from the time of the death of the mother to the delivery of a living child, was seven minutes.

I feel that this method should become the procedure of choice in the class of cases described above where the chance of both mother and child is to be considered, because I feel that the protective value of the flap operation is questionable as a protective measure against infection when really dealing with an undoubtedly infected case.

This method of procedure I have carried out in two cases up to this writing. My success in both cases in securing a living mother and child proves nothing except that it is easily done.

Historical Medicine

The Dawn of Surgery

Obstetrical and Gynecological Operations

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

So many of my notes on the obstetrics of primitive people have appeared elsewhere (1) that the reader is referred there for a fuller account of the subject, to which what I have here to say is meant to be supplementary. Though at the risk of some repetition, I may be allowed to say a word or two more of the wild man's obstetrical operations which preceded his earliest entrance into a state of civilization, if we are permitted to throw the light modern ethnology affords on the dark places of paleology and of history.

It is well known that many if not most primitive women bear their children in a squatting position. Sometimes it takes place in the open or in the bush outside the hut. The Sinaugolo women, sitting on a cocoanut to support the perineum, receive obstetrical care, which in the illustration (Fig. 2) looks efficient and may have been safe enough in the bush (2). One can only reflect that the modern practitioner might think gynecological operations would often be necessary as the result of such obstetrical technic, but this does not seem to be the case. Among some tribes any trouble with the parturient process is blamed on some transgression of moral laws on the part of the woman. Such exceptional phenomena, as well as those of twins or multiple pregnancy, which is a disgrace, so like the animals, were dealt with somewhat in that spirit of intolerance of the temptations and the sins of others, which is a characteristic not wholly absent from the ethics of civilization. One of the first duties of the wise woman of the Bechuana kraal is to twist the neck of a child that has the misfortune to present himself feet first to the world and another is to throw twins into the bush for the wild beasts. Later, if the child is so rash as to cut its upper teeth first, it is put to death, (3) but for all this the primitive midwife acquires skill, dexterity and undoubtedly good judgment from her experience with her patient and the environment. De Sahagun (4) says of the Mexican civilization as the Spaniards found it, that the midwives were very skillful. When she saw the baby was dead in its mother, because it did not move, and the woman was in great pain, the midwife placed her hand in the parturient canal and with a stone knife cut the body of the baby and drew it out by its feet.

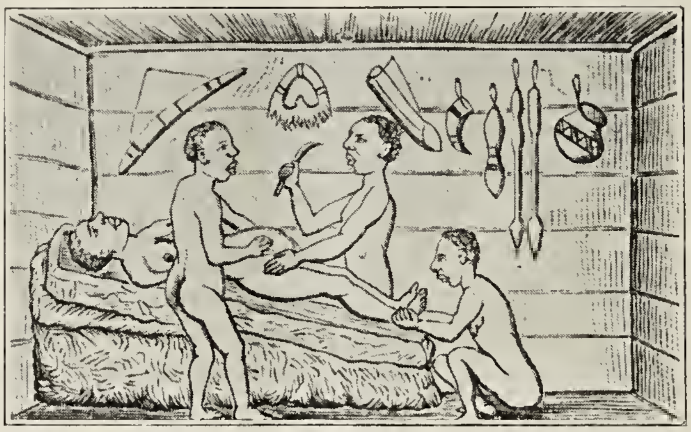

Fig. 1.—Cæsarean section in Uganda. (*After Bartels.*)

Despite the belief that the wild woman has less trouble with her labor pains than her cultured sister, she has them nevertheless and she doesn't like them, though her environment, like faith and fanaticism, tends to force physical pain into the subliminal. They do lead women among a limited number of primitive tribes to attempts to prevent conception or arrest pregnancy. To infanticide she is led usually by other motives than those which actuate the modern woman and her attendant, but the social environment sometimes has its influence also in these directions. Infanticide wounds no moral sentiment in the islands of the Pacific or in China among primitive people, but the desire of man to keep his woman to himself and to stray with the women of other men is well nigh universal, though not entirely so. Moral sentiment in many tribes looks with disfavor on the cohabitation of man and wife once pregnancy is known to have begun and this is the cause of much uphappiness to the woman as her husband seeks other female society. Sometimes cohabitation is frowned on while the woman is suckling the child. The "other woman" in the case is no more welcome in the savage than in the civilized ménage, and this is often a cause exceptionally influential in tempting the primitive woman to actions, immoral and illegitimate in our view, but not always in their own. These are not the only reasons that drive the primitive woman to infanticide and abortifacients, but they will serve to illustrate the sameness and the variations of the question which was apparently not less a problem when man emerged from his cave than when he comes down an elevator from the twentieth story in the twentieth century.

Among the islands of the Pacific instrumentation to interrupt pregnancy is almost everywhere practised, nearly half the pregnancies being thus terminated. In the Fiji Islands where midwifery is a distinct profession, exercised by women in all the towns, the observer also finds them very skillful. In the time of the Horatio Hale (5) exploring expedition it was said if the herbs did not work the destruction of the child *in utero,* it was to be strangled before it left the parturient canal, and this often on the insistence of the father that it should be brought forth dead. "Foremost among the mechanical means is the *sau,* which is a skewer made of losi-losi wood or a reed. It is used of course to pierce the membranes and in unskilful hands it must be a death dealing weapon," but with the knowledge of anatomy and the adroitness these women possess it is probable that not very often disaster results.

The operation very frequently is carried out while the patient is bathing in the sea (6).

Of the more legitimate operations of the accoucheuse of the primitive woman, or of those which seem more legitimate to our moral sentiment, I can not find room further to speak, but I may allude to laparotomy, which it is interesting to observe we find recorded as always the work of a man operator, even in labor cases. They had heard at least of laparotomy in extreme northeastern Asia, since Bogaras (7) found the shamans among the Chukchee pretend to do it with magic, in which a hot knife plays a part, but whether the medicine man had introduced some feat of modern surgery, transmitted from afar, into his hocus pocus, or whether there was a primitive laparotomy and whether he really ever does what he pretends, does not appear in the record. Bancroft (8) says an Indian guide told him he had seen the abdomen opened and a piece of fat cut out, sewed up again and the patient recovered from whatever symptoms he had. A Chippewa Indian was reported to have operated on his pregnant wife by Cæsarean section with good result, both mother and child surviving. The most striking accounts however we get from central Africa. Felkin (9) while camping among the natives of the Bari district was aroused in the night to witness such a performance and the vividness with which he portrays the scene is more than of surgical interest—it is dramatic. He says it is frequently performed in that neighborhood for delayed labor and sometimes it is successful. He tells of a case coming under his observation at Kahura in 1879, in which both mother and child were saved. One can hardly regard this practice as derived from civilized surgery since at that date it would have been difficult for a naked savage African to secure a training in it even in the best university centres of the civilized world. Felkin, indeed, surprised the natives by avoiding a Cæsarean operation on a woman by the use of the obstetrical forceps in public before an admiring group, but now the knife almost bids fair to supplant the forceps. Are we returning to savagery?

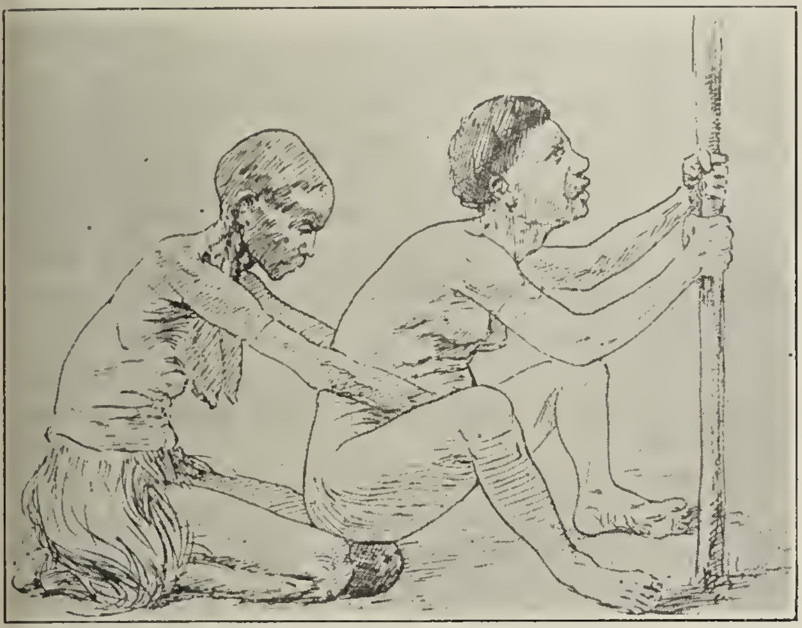

FIG. 2.—The medicine and surgery of the Sinaugolo. (*After Seligman.*)

Budge's tendency to put an African stamp on everything Egyptian, a tendency entirely justifiable unless too exclusively followed and there is strong presumption against it, led him not only to locate the Isles of the Blest in Lake Victoria but to make of Isis an African woman, because of her way of bringing forth children (10). On one of her representations he remarks: "The object on which Isis is seated suggests that during labor she sat on a stool, as women do in West Africa, and did not kneel as do Pygmy and Lendu women," and he is guided by the custom in Uganda when he says: "From this we learn that the umbilical cord of Osiris was cut off and that this cutting symbolized an act of purification, whereby the god was freed at his birth from impurity. In the Westcar papyrus we are told that when the three sons of Rettetet were born the four Meskhenet goddesses, who were present at their birth, washed in turn each child, cut off his umbilical cord, and placed it in a four sided cloth, which was laid in a stone box."

I wish to take this opportunity again to draw attention to the four sidedness of the Egyptian mind, here exemplified by the four attendants and the quadrangular cloth. It stood indeed four square to all the winds of Heaven, just as do its marvelous buildings. In previous articles in various journals I have referred to this and especially I have attempted (11) to show that it is more than suggestive of an influence on the birth of Greek cosmic philosophy and medical theory. The elements were four—earth, air, fire and water—and when ether was invented in that far away epoch it found no place for itself but had to be an adjunct of fire. It was not admitted into the tetrarchy, despite its manifest claim, for then in the existing state of physics it had as good a claim, almost, to reality as air. There were four humors, but to make out the four, they divided bile into two, yellow and black. There were four qualities, four colors, and weights and measures today still show in our own English the trend of the Egyptian mind to a tetrarchy. For Egypt drew its nourishment from the African bush and transmitted more than one trace of negro culture to European civilization.

Now in this Roman birth scene (Fig. 3) we find no trace of four attendants and were it not that one of the figures seems to be a male slave we would think that we find in it a trace of the Eilythyiæ. There was a town in ancient Egypt so named and this was the name under which archeologists have made us acquainted the most ancient Greek goddesses of childbirth. When we seek out three of them we

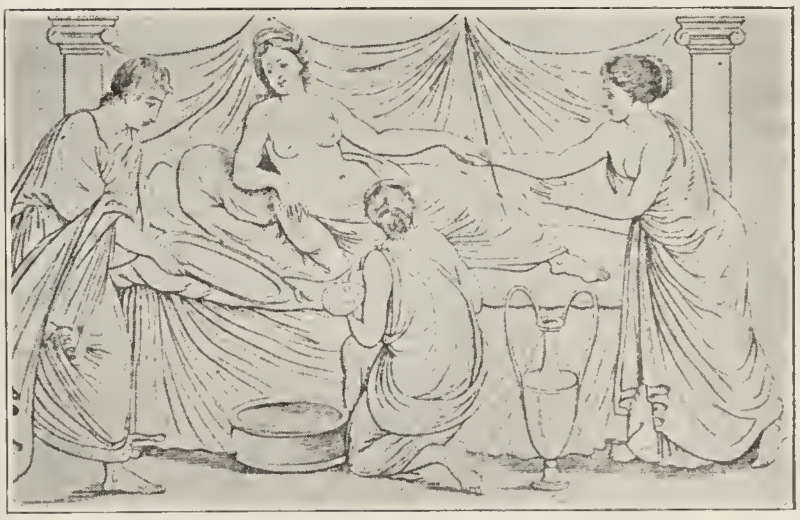

FIG. 3.—A Roman birth scene, from a wall painting.

do not always find just that number, but there are more than one of them usually and we have every reason to believe, that they are the lineal relatives of the Meskhenet goddesses attendant on Rettetet, whose name modern egyptologists attempt to spell in many ways. There are certain things, indeed there is a very large majority of the themes we find in the history of Greek civilization, that we trace back to the Egyptians and the Babylonians. On the whole, however, that is not strikingly true of Greek religion, as Farnell insists with moderate emphasis (12). Certainly the Egyptian tetrarchy was changed into a trinity, because for the European three is a lucky number, just as in China five is the favorite and everywhere seven is the choice in magic. When Herodotus and the Greeks of his time and those who came after him met with foreign gods on their travels and when they were subsequently domesticated at Rome identification was strained to make them seem familiar. Eilythyiæ is mentioned as one person once in the Iliad and subsequently once or twice - the plural use of the word is to be noted (XI. 270), but always assisting at childbirth. It was by the aid of the mutliple Eilythyiæ that Hera outwitted Zeus, the old sinner, both as to the birth of Herakles his son by Alkmene (13) and of Apollo his son by Leto (14).

In the matter of the myth which recounts the childbearing of Isis, when Horus was born, Budge (10) believes he sees a Sudani custom. She took refuge in the bush and was delivered there, but we have seen that the isolation of the parturient woman is all but universal among primitive peoples. The same may be said of the position assumed by the Egyptian women. "Certain pictures show that they either crouched on a bed or a mat with their legs bent under them, or sat on a chair which appears to be in no way different from an ordinary chair. The women who assembled to help took different parts. One placed herself behind the patient and clasped her round the body with her arms during the pains, thus affording her a firm support and assisting expulsion; the other placed herself in front of her, kneeling or crouching, ready to receive the infant in her hands and prevent its falling roughly to the ground. The two goddesses, Isis and Nephthys, come to assist Rudîtdidît, acted like the ordinary midwives, and Hiqaît hastened the birth by massaging the womb, as is still done by the Egyptian midwives of today" (15). This is closely African in its details, but not varying much from the lying-in customs of other primitive people. It is said a votive statue of a parturient woman in a squatting posture is among the objects from Cyprus in the Cesnola collection (16), and this was without doubt the posture in the earliest Egyptian times before the adoption of the birthstool, and probably obtained throughout the Mediterranean peoples in the Stone Age. Following the rule among uncivilized people and the Orientals, the function was presided over by females, perhaps especially trained for the purpose. The birthstool used by the Egyptians was a chair of somewhat horseshoe shape giving support to the gluteal regions and leaving the opening of the parturient canal unobstructed (17). After the umbilical cord was cut and tied the child was laid on a stone originally for the purpose, von Oefele says, of seeing whether it should be allowed to live. The orders of the Egyptian king to kill the male children of the Israelites given to the midwives probably had some precedent, perhaps like the Spartan custom, in a more savage age.

The Hebrews according to the revised rendering of the Old Testament used birthstools (Ex. 1. 15-19). It seems to have been a substitute for the knee of the husband or of the midwife, but birthstones are mentioned in Babylonian literature and Jastrow (18) insists that is the correct rendering of the word in the Bible, similar to the stone upon which the women of the Semites still squat in Palestine while giving birth to a child. One may well conjecture, though the critics pass it over, that there is some reference to birthstones in Hesiod (19). It seems a protest against some old custom:

> "Set not a twelve day boy or twelve month boy
> On moveless stones; they shall his strength destroy."

though it may have had something to do with measuring the child.

We need no link of a pictorial kind to convince us whence the Greeks derived their midwifery, even if they largely manufactured their own medical theories and religious doctrines. A perusal of the books of the Hippocratic Corpus on the *Diseases of Women*, on *Generation*, on *Sterile Women*, will reveal to the critical reader many passages that are parallels or almost copies of some of those to be found in the Egyptian medical papyri now in our hands. The description of the operation of subfumigation, i. e., fumigation of the womb socalled, we recognize as of Oriental origin. Herodotus says (20) some such procedure was practised by man and wife after coition among the Babylonians and in the Egyptian records of gynecological treatment we find the same technic as we find in the books of the Hippocratic collection; so also as to the use of pessaries. Ordinarily we should not take too literally the conventional conception of the transmission of culture from one civilization to another. It resembles too closely the modern man's thought of how an idea is put in a book which is put on a steamer and is thus transmitted direct from Berlin or Paris to New York. The process was not so simple as that, but we are permitted at least to believe that very much the same ideas prevailed and very much the same technic was used in obstetrics and gynecology in the basin of the Mediterranean and its hinterlands by the practitioners of the ancient civilizations there.

CHINESE OBSTETRICS.

A Chinese Household Manual of Obstetrics.—J. Preston Maxwell, of London, and J. L. Liu, of Peking (*Annals of Medical History,* June, 1923), contribute an interesting article on a book picked up by them, which it is said was written by a Chinese scholar in 1661, dealing with the practice of obstetrics in China at that period.

The work is divided into two parts: The first opens with a general statement, briefly discusses life in general, and then takes up the question of labor; things to be avoided; false pains; and ends up with a few case histories. The second part covers sections on the fetus; food for the pregnant; abortion; the puerperium; stillbirth; retention of the placenta; lack of milk; and ends up with maxims and prescriptions. The author is much concerned about false pains and insists that the woman must, 1, sleep; 2, bear the pain; and 3, let the confinement proceed slowly—advice not at all out of place today.

The patient is not to walk about too much and get exhausted, but should try to get as much sleep as possible. She should lie on her back so that the child may rotate easily, and it is pointed out that when the mother is lying down, so also is the child. The following are given as indications of the time when it is right and proper to bear down:

1. The presenting part is really pressed on the perineum. 2. All the joints are loosed. 3. The chest is depressed. (Presumably the meaning is that the uterus had descended.) 4. There is a heavy dragging sensation in the abdomen and back. 5. There is frequency of urination and defecation. 6. There is gleam of the eyes. The author is specially insistent on noninterference.

As to the general care of the fetus, the writer forbids intercourse in pregnancy, advises moderate exercise for the mother, and the view is put forward that abortion is rarer in country women than among the rich, because the former have strong bones and muscles from exercise. He advises an abdominal belt seven inches wide to support the wall during pregnancy, and states that the patient is to be careful to sleep on both sides so that the fetus may become used to both positions. As to diet, the pregnant woman ought to have thin, soft, light food, but he states that this has to be modified for the rich as they will not stand it.

During pregnancy the Chinese physician forbids the patient to see all cruel and wicked things, the digging of foundations, the commencing of buildings, and turtles or rabbits.

Concerning abortion, he insists that it is not to be disregarded. He considers it a more serious condition than normal labor. The most fatal cases are due to careless aftertreatment. He calls sepsis weakness of blood and gives as its symptoms fever, a flushed face, red eyes, great thirst, and restlessness. If it is mistaken for a feverish cold and cooling medicine is given, the patient will certainly die. With regard to the puerperium, directions are given as to the posture of the patient after labor. She is not to be allowed to fall into too deep a sleep, draughts are forbidden, and a routine drug of boy's urine and wine is to be taken for three days.

The author is quite emphatic that the question of having a boy or girl depends entirely on the husband, but he gives no reason for his views. He mentions the killing of female infants to deprecate it.

The following indications of the death of the child *in utero* are given: 1. Flushed face and blue tongue on the mother's part indicate that the mother will live but the child is dead. 2. Bluish face and flushed tongue on the mother's part indicate that the mother will die but the child will live. 3. Bluish face and blue tongue on the mother's part indicate that both mother and child will die."

Some of the prescriptions given are very quaint. A few are given below.

Purple wine. For backache during pregnancy.
Black bean q.s.
Wine, 1 bowl. Take as decoction in the morning.

Yü Feng San 愈風散 For convulsions in the puerperium, shock, diarrhea and vomiting.

Ching Chieh Hsü 荆芥穗 Three drams salvia plebia.
Boy's urine q.s.

Kai Wei Kung Kwei T'ang 加味芎歸湯. For stimulating the fetus.

Tang Kwei 當歸 One ounce Japanese root, ligusticum acutilobum. Chinese root, angelica anomala.

Chuan Kung 川芎 Seven drams conioselinum univittatum.

Kwei Pan 芡寔 Back of turtle, about a hand piece, baked with vinegar and ground to powder.

Editorial Articles

PROBLEMS IN OBSTETRICS

The practice of obstetrics is replete with problems, some of which have been solved, some partially solved, and others yet unsolved. As a rule, in civilized countries obstetrical practice is not particularly successful, not nearly so successful as it should be. Dr. Thomas Watts Eden, of London, in an address delivered in New York before the alumni of the New York Lying-in Hospital on March 2d last, pointed out that the average mortality rate in Great Britain is still about five in every thousand births; and that during the past ten years, this mortality rate has remained stationary, showing little or no improvement.

In this country matters are but little better. According to Dr. W. W. Chipman, professor of obstetrics and gynecology at McGill University, writing in the *Canadian Medical Association Journal* for June, the causes of this high maternal death rate are not far to seek.

Dr. George M. Boyd, of Philadelphia, made the statement recently that nine tenths of all mothers in America receive no antenatal care; that forty per cent. of the women of this country are attended by midwives or unqualified medical practitioners; that the general mortality in childbirth is second only to that from tuberculosis, and that nearly half of the deaths are due to sepsis. Similar conditions prevail in Great Britain in which country antenatal care is in its infancy, although its great importance is beginning to be realized, and more than half the mothers are still delivered by a midwife.

Chipman is of the opinion that if obstetrical practice is to advance at all, it must be along the lines of preventive medicine and this progress may be defined in the following terms: 1, Definite antenatal care; 2, hospital segregation of the complicated cases: 3, simple, efficient technic during labor; 4, postnatal care.

In a pamphlet published a short time ago written by Sir George Newman, chief medical adviser to the British Ministry of Health, dealing with the new methods of practising medicine, it was pointed out that these methods are or would be mostly of a preventive character. The point was stressed in this pamphlet that the safeguarding of the expectant mother was one of the most important planks of this platform, as was also the proper postnatal care of mother and child. Newman appears to be in complete accord with Chipman as to the lines along which obstetrical practice should proceed, and he sketched what he thought an ideal plan for carrying out these greatly needed reforms in this direction. Among the reforms suggested was the establishment of maternity centres in all parts of the country. Moreover the medical adviser to the British Ministry expressed the hope that most of these reforms would come to pass, but he emphasized the selfevident fact that medical education must also be subjected to change in order that practice along these lines might be conducted as it should be. Up to the present time, as a rule, medical students in this country, and presumably in Great Britain also, have not been thoroughly trained in obstetrics. Therefore the first step in bringing about reforms is to render the education of the medical student more thorough in this respect.

Chipman draws attention to a point which is frequently overlooked, namely, that it is essential to bear in mind that in ninety per cent. of all cases, labor is spontaneous, and that, at any rate under existing conditions, a vast proportion of mothers must always be delivered in their own homes. The well trained medical man and nurse must be sent to them and a well adapted and efficient technic must be provided in their own homes.

Sir George Newman and Mr. Chipman, in fact all obstetricians, are agreed as to the necessity for raising the general standard of training for furnishing men more thoroughly equipped and after this has been done ways and means must be devised whereby these higher standards of obstetrical practice must be enforced.

For the benefit of the poor, maternity centres must be provided and, this is most important, the doctor and the nurse must be paid a living wage. Nowadays money is spent lavishly in all directions, but prevention of disease and the saving of mothers and infants in particular is neglected. The public need to be educated regarding the value of measures to eradicate disease and to save and safeguard life and health. Whatever the individual is ignorant of he is indifferent to, and therefore until public opinion is educated to appreciate the value of maternity work, the Government is not likely to aid its progress from the public funds. When public opinion voices itself in favor of maternal and infant welfare being carried on adequately, then and not until then will sufficient money be forthcoming for this purpose. Happily there are signs that public opinion is veering this way.

EARLY DIAGNOSIS OF CANCER OF THE UTERUS

The early diagnosis of uterine cancer is an important question in medical practice, and of all cancers that of the uterus lends itself best to active treatment, upon condition that it can be dealt with as nearly as possible at its onset. Many women with bloody discharges, however, neglect to consult a physician, attributing their trouble to menstrual disturbances, while physicians often reject the diagnosis of cancer when young women present hemorrhagic accidents on account of the apparent excellent health of the patients. The diagnosis of uterine cancer is frequently delayed because of the thread worn idea that its symptoms include hemorrhage, pain, fetid discharge, and a cachectic look. In truth, when these symptoms have declared themselves, the disease is already far advanced.

The first distinctive symptom of the onset of uterine carcinoma is hemorrhage and indicates immediate biopsy. While the characteristics of the hemorrhage are varied, they nevertheless offer some interesting peculiarities. They are irregular and sudden in appearance, coitus or the cannula of a vaginal douche being enough to bring them on. Sometimes they take the form of persistent oozing.

Hemorrhage is also the first and only symptom of epithelioma of the uterine mucosa at its onset and is accompanied by hypersecretion of the glands, which may be considerable. Continued and repeated loss of blood during the intervals of menstruation, no matter at what age, is the first manifestation of carcinoma, while any hemorrhage occurring after the menopause is suspicious and requires a careful examination of the genital apparatus. Unfortunately, at the onset the physical signs are absent, so that one is likely to attribute the hemorrhage to anything but carcinoma.

In the initial phase of cancer of the cervix the examining finger will encounter irregular projections on the surface of the cervix which are less distinctly defined than Naboth's glands and are hard to the touch. Sometimes the cervix is rigid and hard, as if starched, and when an attempt is made to raise up the cervix an effusion of blood ensues—an important diagnostic sign. Inspection reveals a gaping cervix, bright red in color, with small, irregular bosses. Any direct contact will cause bleeding.

It is still more difficult to diagnose cancer of the corpus uteri, which is generally met with in advanced life and in virgins. There is an almost continuous abundant bloody hydrorrhea. Any form of trauma will result in hemorrhage, but the most important evidence of cancer of the corpus uteri is an increase in the size of the organ, at a time of life when atrophy should have taken place. By compressing the fundus a pinkish fluid will be expelled. If a positive biopsy is found, it is decisive, but should the result be negative, it is not convincing, and if the loss of blood persists, clinical considerations should outweigh laboratory findings.

In some women near the menopause abundant metrorrhagias, of the menorrhagic type, occasionally coincide with menstrual irregularity, this symptom being due to old parenchymatous metritis or hypertrophic uterine sclerosis. Syphilis of the uterus may be the cause and all disquieting symptoms may subside if active antisyphilitic treatment is instituted. In some, high blood pressure and cardiac, renal, or hepatic morbid changes are the cause of the loss of blood, and these should be searched for clinically.

Polypous or villous metritides are readily recognized, but certain cancers affecting the polypous type have a large surface of implantation and project through the cervix in the form of a vegetative mass. Senile metritis and uterine cancer may be easily confounded, if only the clinical signs are relied upon, so that microscopical examination of the uterine mucosa must be made.

All things considered, the prophylaxis of uterine cancer rests entirely upon the judicious interpretation of the initial hemorrhage, and any loss of blood occurring during the interval of the menses, if presenting a tendency to be prolonged, frequent, and above all continuous, should exact a thorough examination of the patient.

THE CENTENARY OF MEDICAL JOURNALISM

The first medical weekly journal published was the *Lancet,* which on October 5th last had been in existence for one hundred years. It was issued in London on Sunday, October 5, 1823, by a medical practitioner who had not written previously a line in his life. Thomas Wakley, the man in question, had qualified in medicine recently, was devoid of literary experience, had no particular social standing, no powerful backing, and it seemed as if he had undertaken a hopeless task in his new adventure. But he was impelled by that strong driving force, a personal grievance, and withal possessed sufficient restraint to forbid the feeling to lead him astray. He used the flame which burned in his own breast to excite his energies to introduce reforms into the medical profession in order that others should not suffer in future in the same manner as he had suffered.

With this end in view the first English medical editor worked as a man with but one aim in life, to remove medical abuses. In 1823 his field of work, in this respect, was wide indeed. At that time the medical student in London, or in fact in any part of Great Britain, unless he had money or interest, had small chance of obtaining a satisfactory medical education, and merit had little to do with progress in the profession. The medical profession was unorganized, or slightly and badly organized, and medical education, and to a great extent, the making or marring of a practitioner, rested largely with the honorary staffs of the hospitals. These lectured, examined, and were officers of the Royal College of Surgeons, which body was regarded, at any rate by the profession of London, as the controlling power in medicine, whose word was law. In New England, at the same period, the medical profession was run on similar lines; there was a privileged class and favoritism was rampant.

During the first ten years of the *Lancet's* precarious existence, Wakley was the stormy petrel of medical politics, and devoted his journal to fighting the privileged classes of medicine with every weapon at hand. He attacked them in every possible way, pillorying them before the rank and file of the profession and the general community as betrayers of the public charities, the hospitals, as examiners who drew fees for ineffective and perfunctory work, and as clinicians and lecturers who, as a rule, were beneath contempt.

These men were so strongly entrenched in their privilege, which had become hoary by long custom, that to storm successfully their citadel required unfailing courage and indomitable tenacity. Wakley, who revelled in a fight, possessed such qualities, and finally by his election to Parliament soon after the passage of the first Reform Bill, he transferred the chief scene of action to a place where the aid of legislation could be invoked in his fight for fair play. In 1846 Wakley brought in a bill for amending the law relating to the practice of medicine in Great Britain and Ireland, based on the experience he had gained as an editor. This bill was most certainly his greatest parliamentary triumph, and if he had accomplished nothing else, would serve as a fitting monument. While it had no direct results, as it did not pass, it was the means of the Medical Reform Act of 1855 becoming law, an act which was obviously modelled on Wakley's draft of 1846 in many essential details and which revolutionized the practice of medicine in Great Britain and gave to it its present high professional status.

The first years of the *Lancet* were stirring ones and represented the energetic character of the founder. He was largely instrumental, by virtue of his own personality and the influence of his journal, the vehicle of his views, in immensely raising the standard of medicine. The *Lancet* throughout its history has fulfilled the avowed object of Thomas Wakley and has recorded in its pages all events connected with medicine, surgery, or medical science. Sometimes it has led and sometimes followed, but no striking happening in the medical or surgical world has escaped publication in its columns.

The domestic history of the *Lancet* has been peculiarly fortunate. During the past one hundred years there have been only five editors, all of them Wakleys, except the present able editor, Sir Squire Sprigge, who has held the post for fifteen years.

The history of the *Lancet* is the history of modern medicine. It has moved with the times and yet with a discret conservatism altogether in keeping with British character and tradition. In honor of the occasion a special centenary number of the journal was issued on October 6th, a number well written, well illustrated and well "got up" generally, which adequately commemorates the foundation of the *Lancet* and of modern medical journalism. We greet the green old age of our distinguished contemporary.

NECROBIOSIS OF UTERINE FIBROMATA

It may be said that two types of gangrene arise in uterine fibromata. The first, which belongs especially to exposed fibroids, that is, polypi and submucous fibroids, is due to infections and not to ischemia. It manifests itself by a fetid secretion which may be the starting point of septic complications.

The second type of necrobiosis, formerly called aseptic necrosis, takes place in unexposed interstitial fibroids. It is due to ischemia resulting from strangulation of the neoplasm by its capsule which has become too tight from rapid growth of the tumor, while other observers suppose that it ensues from thrombosis of the veins of the capsule. Bégouin is of the opinion that necrobiosis results from an occlusion of the terminal and single artery, an anatomical condition of some frequency.

When the clinical picture of necrobiosis is complete, a condition not at all uncommon, aseptic necrosis manifests itself by a veritable symptomatic triad, the first of which is pain, often beginning with an acute paroxysm in the lower abdomen which renders it necessary for the patient to go to bed. The condition might easily be taken for a pelvic peritonitis or torsion of the pedicle of an ovarian cyst. This acute paroxysm lasts from three to ten days and then subsides, leaving more or less marked sensitiveness of the tumor, which is increased by pressure.

Should the acute attack be wanting, the patient will complain of spontaneous sensitiveness or pain on pressure.

The second symptom is a sudden increase in the size of the growth, frequently noted by the patient herself when the process consists of a single large fibromatous nodule. On the other hand, the increase in size may not be noticed if there are several nodules, only one of which sloughs. The tumor undergoes softening at the same time it becomes necrobiotic. Thirdly, there is, in most instances, a pronounced change in the general health of the patient at the onset of the attack of pain, with a temperature reaching 108°F. or more. The skin assumes the yellow tinge of sepsis. In some larvata cases, there may be pain only on pressure over the growth.

All this goes to show that the diagnosis is not always an easy matter and must be differentiated particularly from septic sloughing and cancer. On the other hand, one must eliminate peritonitis, torsion of the pedicle of an ovarian cyst, or even rupture of an ectopic gestation. The prognosis, which is less immediately bad than in septic gangrene, nevertheless, can not be regarded as benign when a correct diagnosis leads to immediate operation. Surgical intervention is usually not more serious when there is necrobiosis than in cases of uncomplicated fibroids. The only danger is delay in operating. Hysterectomy is the only rational procedure.

News Items.

Dr. Lorenz's Latest Plans.—Dr. Adolf Lorenz, of Vienna, has resumed the practice of orthopedic surgery at 346 Lexington Avenue, in association with Dr. Dexter D. Ashley, with Dr. Albert Lorenz and Dr. Joseph Nevins as assistants.

Real Medical Library Used in Play.—In *Laugh Clown Laugh,* Lionel Barrymore's new play which is produced by David Belasco, the first act takes place in the office of a nerve specialist. Mr. Belasco's realism is demonstrated by the fact that the library of the physician's office is composed of real medical books furnished by Paul Hoeber, Inc. This was previously done by Mr. Belasco in a Broadway production entitled *The Boomerang,* the medical library being supplied from the same source.

Tuberculosis Conference Well Attended.—The second annual New York City tuberculosis conference was held in the New York Academy of Medicine, and was attended by a large number of physicians, nurses and social workers, as well as by representatives of city and State departments having to do with public health. Bird S. Coler, Public Welfare Commissioner, presiding at a session, stressed the importance of educating the public and declared that the same zeal should be shown for tuberculosis patients as is manifested in the case of some great disaster.

Dr. Charles Fama Honored.—Dr. Charles Fama, examining physician of the United States Pension Board, was the guest of honor at a dinner given in recognition of his services to New York and the country. Police Commissioner Richard Enright, of New York, was toastmaster.

National Social Hygiene Conference Held.—The annual national social hygiene conference under the joint auspices of the American Social Hygiene Association and the Missouri Social Hygiene Association, was held from November 5 to 7, 1923, at the Hotel Statler, St. Louis, Mo.

Second Harvey Lecture.—Dr. Walter R. Bloor, professor at the University of Rochester School of Medicine and Dentistry, delivered the second Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, November 3, 1923. His subject was The Utilization of Fat in the Animal Body.

Dr. Banting and Dr. MacLeod Win Nobel Prize for Discovery of Insulin Treatment.—The Nobel Prize for medicine for 1923 has been awarded to Dr. F. G. Banting and Dr. J. J. R. MacLeod, of Toronto, for their discovery of insulin. These physicians are the fourth and fifth North Americans to be honored by the award of Nobel prizes for scientific achievements.

Dr. Bentz Opens Buffalo Section of Pathology.—The first regular meeting of the Section of Pathology of the Buffalo Academy of Medicine for the year 1923-24 was held Wednesday evening, October 24th, at 8:45 p. m., at the Hotel Statler, Buffalo. Dr. Charles A. Bentz, of the Buffalo Department of Health and of the faculty at the University of Buffalo, read a paper entitled Studies in Diphtheria.

Russian Medical Journals at New York Academy of Medicine Library.—The Russian Public Health Service, with offices at 18 East Forty-first Street, announces that they receive regularly medical publications from Russia and that Russian physicians, as well as American health agencies who wish to make use of these publications, are invited to do so. They are all filed in the New York Academy of Medicine library.

American Electrotherapeutic Society Officers Elected.—At the recent annual meeting of the American Electrotherapeutic Association, September 18th to 21st in Atlantic City, Dr. Sinclair Tousey, of New York, was elected president; Dr. Frank E. Peckham, of Providence, R. I., and Dr. Frederic de Kraft, of New York, trustees; Dr. Richard Kovacs, of New York, was reelected secretary, and Dr. J. Willard Travell, of New York, treasurer.

Association for Control of Cancer Organized.—The American Association for the Study and Cure of Cancer has been organized in the New York Academy of Medicine. This new organization embraces over sixty charter members enrolled from eighteen different States as well as from other counries. At the first meeting on October 12th, Dr. L. Duncan Bulkley was elected president; Dr. Curtis Frank Claassen, of Brooklyn, vice-president; Dr. A. Hirst Appel, Colonel in the Medical Corps, United States (retired), secretary and treasurer; with an executive committee of five. The next annual meeting will be held in Chicago in May, during the meeting of the American Medical Association.

LONDON LETTER.

(*From our own correspondent.*)

LONDON, *August 8, 1923.*

THE CHILD WELFARE CONFERENCE IN LONDON.

The Conference on Child and Infant Welfare, held in London a short time ago, was well attended and some remarkably good papers were read. One of the main subjects of discussion was the maternity question. Childbirth in this country is in a very unsatisfactory condition. A recent pamphlet written by Sir George Newman, chief medical adviser to the Ministry of Health, and issued by that body, referred to this branch of medicine or rather surgery, and points out that reforms are urgently called for, not only in the practice of obstetrics but in the teaching of the same.

MATERNITY HOMES.

A paper on the value of maternity homes in a maternity and child welfare scheme was presented by Dr. W. Allen Daley, and Dr. A. Leyland Robinson, in which they discussed the precise value to maternity and child welfare schemes of the small maternity home of from six to twenty-five beds. It is pointed out that the object of these homes is to bring about a reduction in maternal mortality as well as a decrease in antenatal, intranatal, and neonatal mortality. The Ministry of Health official figures showed that there has not been the reduction in maternal deaths from sepsis or other causes associated with childbirth that has characterized the general death rate, the death rate from infectious diseases, or the infant mortality rate, but remains approximately what it was twenty-five years ago. There was no evidence of reduction in the number of stillbirths. Causes of maternal mortality might be thus analyzed: 1, Sepsis, 1,171 deaths in England and Wales in 1921; 2, toxemias, 604 deaths in 1921; 3, shock or mechanical difficulties; 4, hemorrhages, 469 deaths in 1921, two fifths being due to placenta previa; 5, intercurrent diseases. Another large group of deaths, 262, were due to puerperal embolism and sudden death.

PREVENTABLE DEATHS IN CHILDBIRTH.

The paper went on to say that at a conservative estimate there were over two thousand preventable deaths of mothers in childbirth every year, associated in the main with lack of skilled assistance when needed in pregnancy and after childbirth. There were relatively few deaths in the Metropolitan Boroughs and comparatively many in the County Boroughs of the north of England, where maternity hospital facilities were notoriously lacking. For every woman who died of puerperal sepsis, four were seriously ill or just recovered. Dr. Gardley Holland reported to the Ministry of Health that fifty-two per cent. of the fetal deaths investigated by him were preventable. A study of statistics indicated that a considerable number of deaths of infants under one month could be prevented. Undue prolongation of labor was a frequent cause of neonatal death, and a large proportion of such deaths were also due to prematurity. The prevention of maternal deaths would also prevent many deaths of infants. The most important cause of these preventable deaths was ignorance on the part of expectant mothers that antenatal care was necessary. Many midwives and even doctors appeared to be obvious to the need for taking a full history and examining carefully the women who book them for their confinements. In the opinion of Dr. Daley and Dr. Robinson, the best method for creating a demand for antenatal supervision was to establish a clinic for expectant mothers to which midwives could send their patients and where private doctors could obtain a second opinion in difficult cases. Such had been the genesis of many maternity homes, the demand for which had been enormously strengthened by the prevailing housing shortage. Moreover, not only are an adequate supply of maternity homes required but attention is drawn to the fact that as fifty to ninety per cent. of expectant mothers in the English industrial areas consulted a midwife first the efficiency of the outside midwifery service and the attitude of midwives towards maternity homes was all important. The standard of the practising midwife was steadily rising in England, and there was great reason to hope that the newer type of midwife would realize the importance of preventive antenatal work. Cooperation between midwives and the antenatal centres must be promoted by devices mutually beneficial. The general conclusion of the authors was that the Ministry of Health's recommendation that small maternity homes be instituted was wise.

MATERNITY CONVENTION.

Miss Margaret G. Bondfield read a paper on the Maternity Convention, in which she said: "The Maternity Convention provides that a woman employed in industry shall, for six weeks before and six weeks after confinement, be set free from work, be paid benefits sufficient for the full and healthy maintenance of herself and child, and be entitled to free attendance of a doctor or certified midwife, and in a case where she is nursing the child, shall on resuming work be allowed half an hour twice a day during her working hours for this purpose." Miss Bondfield pointed out that the causes militating against healthy motherhood appeared to be, 1, inadequate wages; 2, lack of knowledge regarding maternity, and of skilled advice and treatment; 3, the personal relation of husband and wife.

At the Washington Convention in 1919, the findings on the maternity resolution were not unanimous, a minority report taking exception to the antenatal provision in regard to work. namely, "the right to leave work six weeks before confinement," but was subsequently defeated. This first international charter of motherhood was carried by more than the necessary two thirds majority, and has since 1918 been ratified by eleven countries, among which Great Britain is not. In the view of Miss Bondfield the position of Great Britain is indefensible. The government indicated its objection to be that a ratification would tend to cut across the health insurance and factory acts, and that adequate provision was made under the existing law. But, according to Miss Bondfield, on severe examination each argument of the government breaks down. Actual examination of figures showed that immense sums of money were being spent already under the existing legislation, and the proposals of the convention, if linked up in some way with the provisions of the national insurance acts, would not be too costly, even in these times.

CHRONIC TOXEMIA AND INSANITY.

That there is a relationship between chronic toxemia and certain forms of instanity has been the opinion of some well known medical men for a considerable time. William Hunter was the first to call attention to chronic sepsis. He especially indicated oral sepsis as the cause or the main factor in the causation and development of many chronic diseases and conditions of ill health. Sir Arbuthnot Lane is another authority, who several years ago stigmatized intestinal toxemia, arising from long continued intestinal stasis, as the cause, directly or indirectly, of many diseases, among which were included cancer and some forms of mental disorder. Dr. William Ford Robertson, late pathologist to the Scottish Asylum Board, who died recently, during the last few years of his life took the deepest interest in the problem of physical causes of insanity and devoted a great deal of his time to investigations in this direction with regard to dementia precox. He seemed to be quite of the opinion that the most reasonable cause of this form of mental aberration was an infection and of the modes of infection he thought that infection of the intestinal tract was the most likely. The death at a comparatively early age, fifty-five, of Dr. Ford Robertson is greatly to be deplored. He was an original thinker and a patient investigator, one not likely to be led astray by a will o' the wisp, and therefore his opinions were especially valuable. It is to be regretted that he had not lived to carry his researches further.

Another Dr. Robertson, Dr. White Robertson, of London, has been pursuing investigations on somewhat similar lines and has just finished, in a paper to the *Practitioner,* for August, the results on some of the surmises suggested to him by investigations into the possible connection between intestinal stasis and epilepsy. These investigations appear to convey to him the view that there is or may be such a connection.

Still another British alienist who has been making investigations, clinical and otherwise, in the same direction, is Dr. Graves who is in charge of an asylum in Birmingham. He also seems to be favorably disposed to take the view that chronic sepsis plays an important part in the causation and development of mental disorders of a certain kind.

On July 11th last, Dr. Henry A. Cotton, medical director of the New Jersey State Hospital, Trenton, read a paper on chronic sepsis in mental disorders, before the British Medico-Psychological Society in London. In this paper Dr. Cotton narrated his experience in treating mental patients from the point of view that they were suffering from chronic sepsis. His experience and those of his colleagues were highly favorable to the view that septic foci were responsible or largely responsible for the mental symptoms, as on the removal of these the percentage of cases of recovery at Trenton more than doubled. Dr. Cotton's paper has aroused much interest among psychologists and those concerned with investigations into and the treatment of mental disorders here.

ROCKEFELLER MEDICAL FELLOWSHIPS.

The Medical Research Council has announced recently the award of Rockefeller Medical Fellowships, tenable in the United States of America during the academic year 1923-24, to the following: John Crighton Bramwell, M.D., Camb., M. R. C. P. medical registrar and registrar to the cardiographic department, Manchester Royal Infirmary; Norman McOmish Dott, M.B., Ch.B., Edin. F. R. C. S. Edin. assistant in the physiological department, University of Edinburgh; Helen Ingleby, M.B., B.S. Lond. M. R. C. P., assistant physician to Victoria Hospital for Children and South London Hospital for Women; Hugh Kingsley Ward, M.B., Sydney, D. P. H., Oxf., member of the scientific staff of the Medical Research Council and working in the department of pathology, University of Oxford.

HOUSING IN LONDON.

The housing problem in Great Britain in general, and in most of the big industrial centres in particular, is acute and the lack of decent housing facilities is responsible for a good deal of the disease, physical, mental and moral, which is prevalent. The recently published report of the 1921 census throws much light on the present housing problem. In 1911, there were in the London Administrative County 678,712 structurally separate buildings occupied, and in 1921, 716,450 or 4.1 per cent. more. It may be pointed out that the increase in the number of separate buildings occupied was covered by the reduction in the interval in the number of dwellings vacant. In 1911, 47,260 structural separate dwellings were returned as vacant while the number in 1921 was 18,969, a reduction of 28,291, or 60 per cent. There were in the area 1,023,951 private families in 1911 and 1,120,597, or an increase of 9.5 per cent. in 1921. Therefore it is obvious that the increase in the number of private families has been larger than the increase in the number of occupied separate dwellings, and consequently the average number of private families to the occupied dwellings has increased from 1.51 in 1911 to 1.59 two years ago. Of the total number of families residing within the area of the Administrative County of London thirty-eight per cent. live in single occupation of separate dwellings, while thirty-two per cent. are families living two to a dwelling and thirty per cent. are families housed in dwellings containing three or more families each. These separate dwellings are of varying size: 18.1 per cent. contain three rooms or less, 27.2 per cent. four or five rooms, 43.3 per cent. six to eight rooms, and 12.4 per cent. nine rooms or more.

London at the present time is less densely housed than in 1911. This is largely owing to the reduction in the average size of the family. The average density for the whole of the administrative county of London is .96 rooms per person, but this is a mean of variations in individual boroughs varying within wide limits.

In those districts in which the accommodation to each person is lowest, the proportion of juveniles in the population is highest. In other words, in those areas in which there are proportionately the most children housing conditions are the worst.

Also it must be borne in mind that thousands of families are living in slum areas or in unsanitary and unsatisfactory dwellings.

In some other of the industrial districts of Great Britain housing conditions are even worse. Glasgow holds an unenviable position in this respect. Owing to the high cost of building the prospects for improvement are not encouraging. Legislation to better the existing state of affairs is of a compromise character, which will render further legislation inevitable before long. The post of Minister of Health is beset with difficulties, of which the housing question is the chief.

GENEVA LETTER

(From our own correspondent.)

GENEVA, *August 25, 1923.*

IMMUNIZATION AGAINST TUBERCULOSIS

In an admirable report recently presented to the Swiss Tuberculosis Association, Prof. B. Galli-Valeiro, of the University of Lausanne, refers at length to the subject of specific immunization in tuberculosis. All who deny the possibility of such an immunization base their supposition on experimental work on the guineapig. Now, in the guineapig tuberculosis develops so rapidly and intensely that no comparison can be made with its development in man. The guineapig is extremely sensitive to experimental infection and almost refractory to spontaneous injection. Nevertheless, in this same animal laboratory men of the first order, such as Kitasato, have been able to obtain cures and immunization with tuberculin.

Others deny immunity because they have not found antibodies in the blood of animals immunized with tuberculin, but in this respect they seem to confound conjointly all the different immunities. If to admit immunity one depended exclusively upon the presence of characteristic antibodies in the blood, immunity must be denied in many diseases and thus renounce the use of many curative and prophylactic sera. Therefore, notwithstanding those solid immunities observed in vaccination for hydrophobia and variola, the antibodies are extremely scarce in the blood. This applies also to antianthrax serum which acts perfectly although devoid of bacteriolysins. There are still many points in the phenomena of immunity which escape us, and it is impossible to include all cases of immunity in the same class. In this respect Galli-Valeiro accepts Petruschky's opinion rather than attempt to establish immunity exclusively on the verification of specific antibodies, which would expose one to serious mistakes.

In tuberculosis the immunizing substances appear—according to Wolff-Eisner, Wassermann and Neufeld—to be seated in the tissue of reaction which develops around the tuberculous focus, so then the bacillus is, so to speak, isolated from the rest of the organism on which it no longer exercises any action. Hence it is not blood immunity but cell immunity which plays the most important part in the defence of the organism against tuberculosis. This is also demonstrated by the fact that a strong maternal immunity is not transmitted to the products of conception.

This does not imply that no antibodies are to be found in the blood of tuberculous subjects or individuals immunized against the disease, because Römer, although unable to verify *in vitro* the presence of bactericidal substances in the blood of strongly immunized sheep, Behring, Vallée, Much and Leschke and Sata have demonstrated that the blood of strongly immunized animals can protect other animals from tuberculosis.

The blood of tuberculous subjects contains specific substances fixing the complement and Galli-Valeiro has shown that in several cases these substances increased by treatment with tuberculin. Likewise the changes occurring in the opsonic index, agglutination and specific precipitation in tuberculous patients treated with tuberculin or emulsion of bacilli, speak in favor of the formation of a certain quantity of antibodies capable of being thrown into the circulation, although the greater part remains localized in the cells surrounding the tuberculous focus. It is also this insufficiency of circulating antibodies that so far has prevented the production of sufficiently active antituberculosis sera.

Although it is quite possible to produce immunizations with tuberculin, because this substance appears to be endowed with the power of liberating active substances of the tissue of reaction around the tuberculosis foci, and in certain animals to provoke the formation of circulating specific antibodies—a fact confirmed by Löwenstein and Pickert, Hamberger and Monti, even in tuberculous human subjects treated with tuberculin—Galli-Valeiro believes that one should attempt to obtain for specific immunization against tuberculosis an antigen containing all the active principles of Koch's bacillus, in as pure a state as possible. For that matter, this is the principle upon which is based all modern vaccinations, excepting those resulting from bacteria having a filtrable toxin, such as diphtheria, tetanus, and botulism.

Consequently, taken by itself, although helping much, tuberculin cannot solve the problem of specific immunization against tuberculosis. The emulsion of bacilli already represents an enormous progress, because it contains all the component parts of the bacillus; however, the true solution will not be found until it has become possible to obtain absolutely attenuated cultures that are unchanged in so far as their antigen power is concerned. For that matter, this is the principle which has directed the numerous attempts of antituberculous vaccination in cattle.

To attain the desired end one may resort to: (1) Spontaneously attenuated bacilli, such as the acid resistant or bacilli of coldblooded animals. Unfortunately, these forms do not appear to possess much value in respect to mammalia, as far as antigens are concerned, and, judging from experiments now being carried out by Galli-Valeiro and Bornand, large doses, lysed in the organism, may even produce death from intoxication.

(2) Human bacilli attenuated by successive strains through coldblooded animals. This is the principle of antiphymatol and Friedmann's vaccine, an excellent one, because it is derived from variola vaccination, experiment antirabic vaccination, etc. But it is not certain that this procedure will result in perfect attenuation and moreover it is doubtful whether or not Friedmann's baccillus is an attenuated Mycob. hominis, rather than a bacillus special to the turtle.

(3) Human bacilli attenuated by different procedures. This is the method followed at present and probably brings us nearer to the desired result by producing vaccines offering the required properties, namely, devoid of danger yet capable of producing immunization. This is the method employed by Shiga with tryptaflavine vaccines, Moro with Eletebine's ointment, Selter with cultures heated at eighty degrees centigrade with phenol at 0.5 per cent. (vital tuberculin), Raw with cattle and human vaccinations with cultures attenuated by age (stub cultures renewed since 1906) and Calmette and Guérin's bile cultures.

Therefore, the solution of the problem is in sight, although for the present one must not be indulged in too much optimism.

LETTER FROM THE CANAL ZONE

(*From our own correspondent.*)

BALBOA HEIGHTS, *October 1, 1923.*

MEDICAL ASSOCIATION OF THE CANAL ZONE.

The Medical Association of the Isthmian Canal Zone held its 198th meeting in the Administration Clinics Building of Ancon Hospital on May 18, 1923. Dr. J. L. Byrd, the health officer of Cristobal-Colon, presented A Résumé of the Antimalarial Campaign at Cristobal-Colon, 1917-1922, and Dr. D. P. Curry, the assistant chief health officer, gave a lantern slide demonstration of the field work of the division of sanitation. Dr. Byrd pointed out that Cristobal-Colon, once known as one of the most unhealthy seaports in the world, is situated on Manzanillo Island near the Atlantic entrance of the Panama Canal. The island was once a tidal swamp but has been largely filled. In 1905, General Gorgas and his coworkers eradicated yellow fever from this area and by 1917 the antimalaria campaign had been extended to about half a mile from the inhabited section. This belt was made thoroughly sanitary, all vegetation being kept closely trimmed, the swampy areas either filled or drained, and the drains oiled at regular intervals of seven days. This eliminated anopheles breeding from Manzanillo Island and the adjoining Mt. Hope district. Nevertheless, malaria continued.

On investigation it was found that countless numbers of anophelines were being bred in the extensive swamps which surround the city on three sides and during 1917, 1918 and 1919 appeared in such quantities on the screens at Colon Hospital and the Washington Hotel at the beginning of the rainy season and for the following three months that it was necessary to detail a laborer to kill them with larvacide applied by a knapsack spray. These mosquitoes came from the swamps two miles distant across Manzanillo Bay, a mile of open water. Flight observations clearly indicated that they would fly against an eight mile breeze for a distance of two miles. The drainage of these swamps by sealevel canals in 1920-21 did away with this annual visitation of anophelines. Very little oil was used in controlling mosquito breeding in the swamps in question. Trochas (paths) six feet wide were cut through the swamp at intervals of fifty yards and sea level drains about eight inches wide dug along their centre. The drains were kept free of vegetation. This method was not expensive and has proved very effective, malaria being successfully controlled and practically eradicated from Cristobal Colon.

VIENNA LETTER

(*From our own correspondent.*)

VIENNA, *August 15, 1923.*

REQUIREMENTS OF BEING A SPECIALIST.

The medical faculty, as well as the medical chamber in Vienna, have long sought to solve the question, Who can be called a specialist? The federation of Vienna specialists has been obliged to arrive at a quick decision. Nominally the mighty sick club of the state officials needed specialists. Applications were made by hundreds but only a few were considered adequate, therefore the board of directors of the sick club turned to the federation specialists asking them to recommend specialists of corresponding knowledge. The federation laid down the following rules as to the distinction of being a specialist and recognized by the federation:

1. A specialist is one who practices only in his special branch and does not deal with general practice.

2. Specialists are those who are taken up by the federation of specialists or are regarded as such by same. If a person is not recognized as a specialist by the federation he may apply to the medical economical organization for sending out a committee which is composed of two nonspecialist members sent out by the medical chamber and two specialists sent out by the federation. The president of the committee is a delegate of the medicoeconomical organization. The result of these rules was that all real specialists hastened to become members of the federation, while the unfit ones were forced by the chamber to refrain from calling themselves specialists.

THE SUICIDE RATE IN BUDAPEST.

The year 1922 has shown an increased number of suicides committed and attempted for reasons not far to seek. After her defeat in the war, Hungary has lost about half her territory, and more than half her population; there is very grave trade depression; the change of frontiers has deprived the country of a good part of its industrial markets, and has frequently interfered with family life, while the means of communication which remain are difficult to come by, and the getting passports entails much time, trouble, and expense. Even postal communication with the lost territories is uncertain; a letter travelling ten miles from Hungary into Roumania takes a week or so, owing to the prevailing system of censoring the letters. Under these conditions it is not to be wondered at that the number of suicides in the past year amounted to 516, 10.5 per cent. more than in 1921; of these 368 were men, 142 women and 6 juveniles (three children). The suicides of juveniles are increasing in frequency; The youngest of these six juveniles was eleven, the oldest fourteen. The causes appeared to be desperation at loss of parents and cruel treatment by employers. The oldest person who killed himself was ninety years, the highest number of suicides was 107 in November and ninety-four in December.

Book Reviews

RECENT FRENCH MEDICAL BOOKS

Traité de physiologie médico-chirurgicale. Par Prof. Charles Richet et Dr. Charles Richet, Jr. Paris: Felix Alcan, 1921.

Précis de therapeutique des maladies de la peau. Par Thibierge et Legrain. Paris: Gaston Doin, 1922.

Physiologie Obstetricale normale et pathologique. Par Dr. Henri Vignes. Paris: Masson et Cie, 1923.

La Physiologie normale et pathologique du foie. Par Prof. G. H. Roger. Paris: Masson et Cie, 1923.

It is a striking phenomenon in England and America that book reviewers place their estimate on a foreign work in direct ratio to the number of quotations from American or English writers. The reviewer of the four books listed above is in close touch with current medical literature and his object is to present an analysis of a few recent books that are of unquestionable value and contain sufficient reference to American writers to satisfy any reviewer.

* * * *

Richet's *Traité de physiologie médico-chirurgicale* is an interesting work and is issued in two volumes, together containing 1452 pages and 141 illustrations. In this clearly written book an attempt has been made —and a most successful one—to deal with the subject of physiology from the viewpoint of its application to practical medicine and surgery, and in this lies its value. For the advanced student and the practitioner this is an immense advantage and practical to the highest degree. The science of physiology has developed to such an extent that to be complete a treatise on this subject would necessitate a work of four or five large volumes. Neither student nor practitioner can today pretend to know everything comprised in this science, so the work under consideration is elementary, the author's intention being to deal merely with the facts that are strictly necessary for the physician to know about physiology, which is the basis of medicine.

Many textbooks and systems of medicine give space to physiological experimentation, it is true. Fever, diabetes, syncope, asphyxia and inanition are studied, but these chapters on general pathology remain isolated and are unrelated to normal physiology, which should precede them. However, the study of fever, for example, is the immediate conclusion of a chapter on the physiology of animal heat. Pathology has been enlightened by physiology, and, inversely, physiology has been enlightened by pathology. Far from being discordant, these two sciences are, in reality, in perfect harmony, and those who maintain that clinical medicine and physiology are in opposition to one another certainly never understood either.

The reviewer knows of no work in any language that better fulfils the conditions named, and these two volumes should be cordially received by those who would keep abreast of the times.

The first edition of Thibierge and Legrain's eminently practical treatise on cutaneous diseases appeared in 1895, but for various reasons Dr. Thibierge refrained from bringing out a new edition until last year, chiefly because the properties of the numerous physical agents successively introduced into dermatological therapeutics seemed to him not sufficiently understood. Of late years, however, their technic has been improved and their indications have become clear, likewise their advantages and disadvantages.

In the present volume the author's aim is to present all the elements of treatment of the dermatoses and in this respect they have undoubtedly succeeded. Contrary to the majority of textbooks on skin diseases, which present the various treatments of each lesion without considering their relative value, Thibierge and Legrain have endeavored to bring into relief those methods of treatment in which they have the most confidence. Far from mentioning all the medications that have been proposed for the treatment of dermatoses, the authors have judiciously chosen those which have given them the best results.

The material is well digested and the wide experience of the authors, extending over many years should make the book of special value to those seeking authoritative advice on the treatment of skin diseases.

* * * *

Dr. Henri Vignes's *Physiologie obstetricale normal et pathologique* is unquestionably a unique and valuable contribution to obstetrical literature. The matte contained in its pages is evidently based on th author's personal researches, but he has also quote the most recent work of others on the subject, an for the first time has placed the physiology and biochemistry of gestation and labor in as perfect perspective as the present day scientific data will permit The book possesses great practical value as well as it is a clinical guide to the analysis of pathologica states arising in pregnancy and labor, as well a offering the choice of therapeutic measures appropriate in these states.

The book is divided into three parts. The firs treats of gestation and in fifty pages the author give the first synthesis of physiological and pathologica conditions observed in the endocrine glands durin gestation. In the second part Dr. Vignes present a general theory of uterine contraction and its anomalies, but it is only in the physiological and clinica study of these anomalies that one will find th indications for the use of drugs susceptible of mod fying uterine tissue and contraction. The autho insists that both anesthetics and oxytocics shoul be studied carefully and extensively. The third an last part of the book deals with the postpartu period in a most scientific and practical manner.

All things considered this is a valuable contribu tion to the science and art of obstetrics, the boo being the fruit of long and conscientious study c ample clinical material.

* * * *

La Physiologie normale et pathologique du fo is the work of a master hand. The majority of chem ical changes accomplished by the liver require t presence of glycogen, as Roger demonstrated as f back as 1886. This correlation is easily explained the formation of glycoside transformed by oxid tion into a conjugate glycuronic acid. In combinin with sugar a poison loses its toxic properties and is easily eliminated by the kidneys. Glycogen is not ess useful in a great many other manifestations of hepatic activity, and hence establishes a certain correlation between various functions of the liver. There are also intimate correlations between the liver and other glands, a coordination being assured either by he nervous system or the endocrine glands. These functional synergies explain a large number of morbid sympathies.

Glycogeny, that is to say, the accumulation of glucose in the form of glycogen and the excretion of glycogen in the form of glucose, is governed by a triple mechanism, viz., a nervous mechanism made evident by pricking the fourth ventricle; a humoral mechanism, intervening whenever a change in the sugar tenor of the blood occurs, and a third, hormonal in nature, explaining the influence of the pancreas, suprarenals, hypophyses and thyroid on glycemia and the development of the glycosurias. The study of the normal and pathological physiology of the liver comprises the majority of the functions of the organism and reveals the constant interference of the liver in most of the transformations to which organic matter is subjected.

The eminent author makes no pretention of having written a complete treatise on the liver, but he has attempted to show that considerable progress has been made during the past few years, yet for all that the *éclat* of modern discoveries has not dispelled all the obscurity by which the subject is surrounded.

GYNECOLOGY

Aids to Gynecology. By Richard E. Tottenham. New York: William Wood and Company, 1923. Pp. vii-128.

In this the sixth edition a number of sections have been reprinted almost unchanged. The whole subject of gynecology is treated in mere outlines, very briefly and very conservatively—almost too much so to be of value to any one except perhaps a third year medical student.

OCULAR SYMPTOMATOLOGY

Séméiologie Oculaire. Par Félix Terrien, Professeur agrégé à la Faculté de Medecine de Paris. Paris: Masson et Cie, 1923.

The anterior segment of the globe, especially that part which is presented as the sclerocorneal pole merits separate treatment, as the author reminds us, by reason of its accessibility, the ease with which it can be examined clinically with simple apparatus, and the frequency of its involvement in ocular, as well as in systemic disease. The study of conditions in these tissues in health and under pathological conditions, their normal and morbid histology, anatomy and physiology, must be of value and of more than pasing interest to the oculist as well as to the general practitioner. Terrien has given us such a study in an unusually complete form and interesting manner. The clinical examination in particular, with the use of the ophthalmoscope, the corneal microscope and the slit lamp of Gullstrand, is of great value to the ophthalmologist. The chapters on the physiology of the anterior segment in its relation to intraocular tension are important. The volume also contains a summary of injuries of the anterior segment, wounds and contusions, rupture of the globe, intraocular foreign bodies and their detection by the magnet and radiography. All this, together with the economics of blindness and the causation of sympathetic ophthalmia, the author attempts to present in a few short chapters. Needless to say, not quite successfully.

TONSILS

The Tonsils, Faucial, Lingual, and Pharyngeal. By Harry A. Barnes, M.D. Second Edition. Illustrated. St. Louis: C. V. Mosby Co., 1923.

This study of the lymphoid ring of Waldeyer in its normal and pathological aspects, deals not only with histology and physiology, clinical examination and symptomatology, embryology and developmental history, but with the general pathology and bacteriology of the tonsils and their relation to systemic infections. There is an excellent chapter on tonsil operations, and one on the complications and sequelæ of these procedures. The second edition of Barnes's valuable work presents the latest developments in surgery of the tonsil, such as the capsule splitting operations, and radiation. The chapter on focal infections appears to have been entirely rewritten.

THE UNCONSCIOUS

L'Inconscient. Par. Dr. A. Hesnard. Paris: Libraire Octave Doin, Gaston Doin, Editeur. 1923.

The author's brief but comprehensive survey of the unconscious rouses afresh the wonder that the latter has been so long without its acknowledged place in psychology. Hesnard's point of view is that of a dispassionate psychological inquiry into the place of the unconscious in ontogenetic and phylogenetic development of the mental life, its interrelation with consciousness, both considered as only parts of the same mental life, its indispensable position as the background for interpretation of otherwise mysterious occurrences. These the writer reviews to find that their explanation lies most naturally in the dynamic functioning of that part of the mental life out of sight of consciousness which latter receives only the end product. Psychopathic disturbances are among these occurrences which reveal such activity and which also testify to the affective rather than the rational nature of the unconscious. Various medical theories in relation to the problems of the unconscious are discussed, not the least space being given to Freud's revelations. The author's work is descriptive rather than presenting an estimate of these various modes of approach, yet he both acknowledges the indebtedness of psychology to Freud and to some extent expresses disagreement with him. His very full bibliography, however, adds testimony to the large place Freud and his followers occupy in bringing the unconscious into psychological attention.

PSYCHOLOGY FOR THE BEGINNER

An Introduction to Psychology. By Susan S. Brierley, M.A. New York: Dodd, Mead and Company, 1923.

This book shows how clearly psychology may be presented with due respect to the definitions and methods which belong to the older psychology but with ample room for the consideration of the deeper facts of the human mind which have brought forward both a recasting of definitions and the development of new methods. The author's discussion, briefly simple though its stands, shows how the genetic insight into the things of the mind, the facts with which psychology deals, finds a most natural reconciliation between facts and principles which only superficially appear contradictory. The writer evidently knows her psychology in its more classical aspect and also as a study which includes the unconscious. Her breadth of viewpoint and her clearness of perception form a desirable aim for any would be student or critic of psychology, and they have given here to beginners and others an admirable presentation of psychology which touches its entire scope. It is necessarily brief and elementary. As such it fulfills the author's purpose. But as a direct and unbiased study it clearly points the way to larger knowledge.

HYGIENE OF THE VOICE

Hygiene of the Voice. By Irving Wilson Voorhees, M.S., M.D. New York: The Macmillan Company, 1923.

This little book is one of those written *from* practice rather than *for* practice. It has grown out of the author's experience in examining, advising, and treating singers and speakers. Dr. Voorhees does not assume to discuss the technic of voice production except incidentally to his suggestions for keeping the vocal organs in good condition and avoiding their abuse. His little volume is not only most instructive and of value to the followers of the many vocal professions, and to their would be advisers, but interesting and stimulating as well. It contains much good, commonsense matter presented clearly, tersely, and in admirable style.

OPHTHALMIC YEAR BOOK

The Ophthalmic Year Book. Volume XIX. Containing Bibliographies, Digests and Indexes of the Literature of Ophthalmology for the Year 1922. Edited by Edward Jackson and William H. Crisp. Chicago: Ophthalmic Publishing Company, 1923.

With the year 1923, this publication, which for a time was merged with others to form the *American Journal of Ophthalmology* and later appeared as *Ophthalmic Literature,* now resumes its original form of an annual volume, bringing the references to current literature up to and including December, 1922. With the increasing number of publications in every department of medicine it is becoming more and more difficult to keep abreast of the times in one's reading. A *Year Book* of this sort is a necessity, if only for those who wish to get a complete bibliography on any topic connected with the eye and its diseases, for purposes of reference. But it is much more. The reviews and digests, some of them illustrated, cut down and eliminate a great deal of unnecessary or at least avoidable reading, giving a summing up of all the important publications. *The Ophthalmic Year Book* finally has became a *sine qua non* since the suspended or at best intermittent publication of Michel-Nagel's *Jahresbericht für Ophthalmologie,* the old standby of library workers.

MEDICINE IN WAR AND PEACE

Krieg und Frieden im Lichte der Medizin. Entwurf einer Medizinischen Soziologie. Von Theodore Huzella, Professor an der Universität Debreczen. Berlin: Verlag von S. Karger, 1923.

Of this little *Tendenz-Schrift* one might say "better late than never," if not, *Ex Oriente Lux.* It deals with war and peace and the tendencies of the medical profession, with humanity and its association in the couple, the group or the mass. The social arrangements of human beings in their most manifold expression are seen to have typical but opposite applications in war and in peace, respectively. Huzella's short but exceedingly interesting brochure considers the relation of the physician to this varied activity, the rôle of medicine and of medical men toward masses, cooperating on the one hand, or murderously antagonistic on the other. The whole presentation embodies the reaction and the individuality of a physician to the experiences and impressions of a world at war. Altogether, an unusual and deeply philosophical treatise.

TUBERCULOSIS

Recovery Record for Use in Tuberculosis. By Gerald B. Webb, M.D., and Charles T. Ryder, M.D. New York: Paul B. Hoeber, Inc., 1923.

This is an interesting literary production by two well known phthisiotherapeutists, although the title seems hardly appropriate to the best part of the book; namely, the first eighty pages which contain instructions for the patients to follow. The rest of the book consists of over a hundred pages of blank chart sheets on which the patient is expected to enter his temperature and pulse twice a day, his daily weight, general notes, and the questions he wishes to ask the physician. The reviewer is led to wonder if such daily record taking will not lead to altogether too much introspection. It is a known fact that to make some patients aware of a slight rise of temperature, gives not infrequently a sufficient mental reaction to be the cause of an additional rise.

The first eighty pages of the book are divided into four chapters under the following titles: The Record of Recovery, The Technic of Recovery, Hygiene of Recovery, and Accidents and Obstacles. All the well known instructions usually offered to the tuberculous patients are given in a lucid and interesting way. More than usual emphasis is placed upon the importance of rest.

The authors themselves have perhaps realized the danger mentioned of too much introspection being caused by filling out the daily record sheet, for they have endeavored to put as much optimism as possible in the text and each record sheet is adorned by two quotations collected from authors ranging from those of antiquity up to those of the present time. Graphic sentences from Epictetus, Homer, Sophocles, and Shakespeare, as well as our own Allen K. Krause, Lawrason Brown, and other present day therapeutists, are quoted. Most of these sayings are very appropriate. From Osler is quoted the following: "While there is fever, the patient should rest in bed." From Trudeau: "I know I have hurt nobody by rest; but I am quite sure I often have by allowing them to exercise." Koch's optimistic words are also given: "This is a conflict which we may enter with a surely founded prospect of success." There is one more quotation from Trudeau which because it has so much significance for all tuberculous patients and perhaps also for all physicians treating tuberculosis, the reviewer may be permitted to reproduce here: "The struggle with tuberculosis has brought me experiences and left me recollections which I could not have known otherwise, and which I would not exchange for the wealth of the Indies."

This little volume of Webb and Ryder is a commendable publication for those patients who are resolved to get well and will not take to heart the little variations in temperature and the occasional little losses in weight which are inevitable in the course of this disease. The physician who has such a patient will be glad to be able to recommend this book to him.

Medicoliterary Notes.

The July number of *Health News,* the monthly bulletin of the New York State Department of Health, is a Hermann M. Biggs memorial issue. It contains a sketch of Doctor Biggs's life and work and a series of tributes from many of his friends and colleagues.

* * *

Clothing the Baby is the title of a bulletin recently issued by the Home Economics Department of the University of Wisconsin. Dr. Dorothy R. Mendenhall, the author, makes a plea for simplicity, warmth and lightness of material in dressing babies.

* * *

The National Committee for Mental Hygiene is compiling a directory of all physicians in the country who are practising neurology and psychiatry, with autobiographical information concerning each, so far as possible. . . .This information will be used to meet the demand for the services of such specialists in different communities . . . as well as the increased demand for neuropsychiatrists in institutional positions.—*Mental Hygiene Bulletin.*

* * *

The *Yale Review* for October is a number of unusual interest. Among noteworthy articles are A Playwright's Mind, by Jacinto Benavente; Are Americans Timid People? by Agnes Repplier; New Lights on Egypt, by Sir W. M. Flinders Petrie; and On Contemporary Stupidity, by Hilaire Belloc.

* * *

Dr. C. Armstrong, of the U. S. Public Health Service, has a comprehensive and very interesting article on dengue fever in the *U. S. Public Health Reports* for August 3d.

* * *

The report of a recent meeting of the British Medical Association, at which the much mooted question of "What constitutes health?" was discussed at some length, throws some interesting light on the change in medical opinion that has taken place in the last few decades. At the beginning of the socalled scientific age in medicine, the stethoscope was the instrument upon whose findings judgment was based. Now the index of health is generally conceded to be fitness to carry on daily work without undue physical or mental stress—a far cry from the former socalled medical death sentence type of prognosis.

* * *

A public health educational campaign which is expected to reach several thousand people has been planned by the Illinois Health Department. Every important county fair and all larger fairs are being covered by field units equipped with motor cars, moving pictures, lectures, and other necessaries for conducting demonstrations and exhibits. The programs embrace motion picture shows, poster displays, distribution of literature and superficial physical examinations for adults. A larger number of well baby conferences have also been planned.

* * *

The Illinois Legislature has passed a law making it a punishable offence to maintain or lease houses of ill fame for purposes of prostitution, disorderly conduct, gambling or drinking. The penalty is a fine of not more than $200 or imprisonment for not longer than two years.

* * *

A recent issue of the *National Geographic Magazine* contains an interesting account of a present day Robinson Crusoe, this time including a Mrs. Crusoe, living on Middleton Island off the Alaskan coast, where they have a blue fox farm. Their Friday is an old black horse that had been abandoned to fate by former residents of the island.

* * *

Industrial Hygiene for August has an article by Dr. C. Macfie Campbell on Mental Factors in Industrial Hygiene.

* * *

The proposed exhaust chimney suggested by Prof. Yandell Henderson, of Yale University, as a partial solution of the automobile carbon monoxide problem in large cities, is being widely commented upon, both pro and con, in many of the medical and scientific journals.

* * *

A full and detailed study of some new aspects of tumors forms the leading contribution to the number for June 5th of the *Belgian Annales et Bulletin de la Société Royale des Sciences Médicales et Naturelles de Bruxelles.* Doctor Reding is the author. A bibliography of recent articles on the pathology of tumors is appended.

* * *

The New York City Department of Public Welfare has established as a part of its work a cancer institute, the clinic division of which is situated at 124 East Fifty-ninth Street, and the hospital division on Welfare Island. As the institute is established especially for the benefit of the poor of the city, no charges are made for its work, which includes the complete diagnosis, and the surgical, radium, and high voltage therapy of cancer.

* * *

In a recent number of the *Nature Magazine,* Dr. William T. Hornaday, curator of the New York Zoological Garden, makes a strong plea for protection of the wild life of the country from hunters in automobiles. He declares that their ravages are not sport, but slaughter, and estimates that "the automobile has increased the perils of wild life by fifty per cent." He describes as an example of what has been done in other countries—a warning to America—the slaughter in the first few days of an open season of practically all the long protected and unsuspecting chamois in the Swiss Alps, setting back the species to the original vanishing point. Much hunting of herds of animals and flocks of birds is now done with machine guns carried by automobiles, and as a result many valuable species are threatened with immediate extinction.

Practical Therapeutics

THE MANAGEMENT OF THE COMMON FORMS OF RECTAL DISEASES COMPLICATING PREGNANCY

By Arthur A. Landsman, M. D.,
New York,
Attending Proctologist to the Jewish Memorial Hospital; Deputy Surgeon, Diseases of the Rectum, Out Patient Department, New York Hospital, etc.

In the pregnant woman there is a decided tendency toward the development of rectal disturbances because of the natural changes produced by gestation. The various types of hemorrhoids are the most common, but fissure, abscess about the rectum, fistula, polypi which have become strangulated, and fecal impaction are not infrequently met, and many women date the beginning of what they describe as piles to pregnancy and childbirth. The causes which predispose them to these ailments are to be found mostly in the interference with the local circulation from the enlarged uterus, the congestion of the parts incidental to pregnancy, and the chronic constipation from which so many women suffer at this time—all doubtless accentuated later by difficult labor and aggravated by prolonged involution.

Because of the possible effects of rectal diseases upon the course of pregnancy, as well as upon the general health of the mother, the proper management of these conditions becomes a matter of no small importance. It is well within the bounds of possibility for gestation to be interrupted by an acutely painful fissure or abscess, by extensive thrombosis of the anal veins, or by strangulation of large masses of internal hemorrhoids, while the persistent bleeding which complicates some cases of ulcerated piles can not fail to have a bad effect upon the health of the expectant mother. In view of these dangers, what is to be done for these patients to prevent rectal disorders, and how to treat them should their prevention be impossible, becomes a vital problem.

Although even serious operations have been performed upon pregnant women without interrupting gestation, it is well to keep clear of surgery at this time except in cases of emergency, in which it may be considered as the lesser of two evils. But if operate we must, only the minimum which will afford relief is permissible, all extensive surgery being postponed for a more favorable period.

Much may be done to prevent rectal disturbances in gravid patients, not only by carrying out general hygienic measures, but in the avoidance of certain conditions which prepare a favorable soil for their development. Foremost among these is constipation, by which we understand not only delayed evacuations, but stools which require much straining for their expulsion. Mankind has always found it easier to solve the problem of constipation by taking so much out of a bottle three times a day, than by a systematic effort to regulate the function of the body; but the habitual use of physics is an unmitigated evil which in time defeats the very purpose it is intended to serve. Regulation of the gastro-intestinal function can not be brought about by the use of drugs, but is largely a matter of rational living in which a suitable diet plays no small part. Its essentials are plain, simple, wholesome fare, a generous allowance of fresh fruits and vegetables, plenty of water, fermented milk, buttermilk, etc., and the avoidance of rich foods and stimulants. Rest in the knee chest position two or three times daily to ease up pressure and help the return circulation is a useful measure in those predisposed to hemorrhoids. If an acute attack of hemorrhoidal trouble does occur, the patient is to be put to bed, an oil and water enema given, and the edema treated with cold applications of a solution of lead subacetate, witch hazel or dilute aluminium acetate, with one or two doses of morphine if necessary to relieve pain, lessen nervous tension, and secure sleep. Even marked swellings may often be thus reduced and the patients tided over the acute stage of their troubles.

Prolapsed internal hemorrhoids should be replaced by gentle pressure, and retained by rest, posture and the application of a firm T binder. But if the hemorrhoids have become strangulated reduction is of no avail, and resort must be had to surgery, preferably under local anesthesia, without dilating the anal sphincters. If the symptoms persist and the parts become tender and throbbing, localized infection is to be looked for, and if found, treated by early incision to prevent perirectal burrowing. But here again we are to be guided by conservative principles and limit operative intervention to what is needed to give immediate relief—incision and drainage of the pus cavity. If the abscess ruptures into the bowel or on the skin surface, the openings may be enlarged, but on no account is the fistulous tract to be excised until after delivery.

One of the most annoying rectal affections with which we have to deal is fissure in ano, which, because of the acute pain, the reflex pelvic disturbances which it may cause, and its tendency to become complicated with abscess and fistula, is of especial interest in this connection. If it is of recent origin and not deep, we may be able to lessen its symptoms and even secure permanent relief by a regulation of the diet and local applications of stimulating and antiseptic substances. The diet best suited is one which will aid in forming stools containing a large percentage of moisture. Stools which are watery carry small fecal particles into the bottom of the fissure, and are difficult to dislodge because of the spasm of the muscles generally present. On the other hand, evacuations which are excessively dry traumatize the parts and prevent healing. We advise vegetables and fruits in abundance, and the addition of olive oil, buttermilk, fermented milk, sour cream and plenty of water. Locally, argyrol, nitrate of silver and ichthyol are used in various strengths, but if the symptoms remain unrelieved there is no choice but surgery. A clean cut incision under local anesthesia through the bottom of the fissure, gauze drainage, and rest in bed for a few days will generally give relief. It might be mentioned in this connection that fissure is occasionally found associated with solitary pedunculated polyp of the rectum; if the growth becomes strangulated it is prone to set up much pain and considerable disturbance of neighboring structures by reflex irritation. Naturally, unless the cause of the trouble is discovered, treatment of the fissure alone will be unavailing.

Fecal impaction is likely to occur in those patients who have a tendency to hard stools and chronic constipation, and is aggravated at this time by mechanical obstruction due to the enlarged uterus. Small particles of stool may be passed and these patients often insist that they are not constipated, but digital and proctoscopic examination will reveal the true state of affairs. It is advisable to put them upon a proteid diet, and make an effort to clean out the rectum with enemata of warm water and oil, oxgall, glycerine, peroxide of hydrogen, etc., but if unsuccessful the mass will have to be removed under general anesthesia.

Ulceration of the rectum must be treated with due consideration of the underlying cause, which applies principally to the amebic, luetic, and tuberculous types. Since it is frequently complicated by severe and persistent bleeding, the treatment of the local condition is of primary importance; irrigations and instillations of such substances as silver, quinine sulphate, coal oil, mixtures of bismuth, iodoform and petroleum oil have been used with much benefit.

To summarize the management of rectal diseases occurring during pregnancy, the following may be restated:

1. Suitable care of the intestinal tract as a prophylactic measure.
2. Medical treatment of conditions as they arise.
3. Surgery, if necessary, the keynote of which should be conservatism.

310 West Eighty-sixth Street.

URETEROVAGINAL FISTULA FOLLOWING HYSTERECTOMY

With Unusual Recovery

By Henry A. Bernstein, M. D.,
New York.

Medical literature is not wanting in instances of spontaneous repair of ureteral injuries due to surgical accidents, but a careful search does not disclose any description of an exactly similar circumstance of recovery as the following:

The patient, Mrs. L., came to the operating table in March, 1920, after a severe uterine hemorrhage. She gave a history of almost constant bleeding for three weeks, with a blood picture of 50 per cent. hemoglobin, 3,000,000 red cells, 1,200 leucocytes, and 70 per cent. neutrophiles. She was thirty years of age and had one child, eight years old. There had been no miscarriages and no other pregnancy. An only sister underwent a hysterectomy for fibroid uterus at the age of twenty-eight. On account of the patient's anemic condition a transfusion was considered necessary and she received 800 c. c. whole blood just before the operation, under the direction of Dr. L. J. Unger.

I shall not dilate upon the operation, which consisted of the removal of the upper part of the uterus (the fibroid extended to about an inch and a half above the umbilicus), except to say that all normal anatomical landmarks were distorted and adhesions everywhere made a mess of calculations. During the separation of adhesions a clamp was accidently placed on the left ureter. This was immediately discovered and removed without any apparent evidence of injury. The patient had a stormy convalescence and recovered slowly and with much suffering. A blood count taken two days after the operation showed hemoglobin 70 per cent., red cells 3,500,000, white cells 1,200, neutrophiles 70 per cent.

Five days after the operation the patient complained of feeling wet and very soon urine began to flow from the vagina, forming a lake in the bed and requiring constant attention to keep her comfortable. She was discharged from the hospital three weeks after the operation in a very miserable condition, and continued this way all summer, leaving evidence of her presence wherever she sat or stood. The urine continually showed a large quantity of pus and her body temperature ranged between 99° and 102°. Off and on she suffeed from cramps and burning sensations in the lower back and pelvis, probably due to escape of urine into the pelvic cavity and tissues surrounding the bladder.

On September 16th I examined the bladder by cystoscope but found nothing out of the ordinary, except that the left ureteral orifice appeared puffy and without evidence of any urinary discharge. More from timidity than from any other reason I did not at this time attempt to catheterize the ureter. A blood count was taken September 18th, showing hemoglobin 55 per cent., red cells 3,200,000, and white cells 1,200, with neutrophiles 68 per cent. Urine practically poured out of the vagina and continued to show a large pus content. The patient demanded relief and theatened to terminate her existence.

A second operation was under consideration either for repair of the ureter or the removal of her left kidney, but the operative risk, on account of her poor physical condition, prevented a rash decision. A second transfusion was decided upon preliminary to surgical intervention, and she again received 800 c. c. whole blood, the result of which was a decided improvement in her physical condition, but the leakage of urine still continued.

On October 19th I again examined the bladder with the cystoscope and decided, though with some hesitation, to test the patency of the left ureter by catheterization. A catheter was inserted without difficulty, and in a short time I was pleased to observe a few drops of urine flow from the outlet. I did not at that time attach too much importance to this circumstance, but was delighted when the patient, about a week later, notified me that she was voiding urine in a normal fashion and had not had any leakage since the last visit to my office. She has continued to improve in health and up to the present time has gained forty pounds in weight, and has evidently recovered all the normal functions of her ureters and bladder.

Beyond doubt there was a tear in the ureter near the bladder due to the accidental application of the clamp. This tear, forming a vlave, prevented the urine from that side entering the bladder and allowing its escape into the surrounding tissue where it finally found an exit through the operative wound into the vagina. By insertion of the catheter the valvelike portion was shoved into place and granulation, assisted by the new blood administered in transfusion, caused the wound in the ureter to be closed permanently and the patient was carried on to recovery.

It may not at all times be wise to insert a catheter into an injured ureter, especially if there has been a complete separation of this tube. The danger of carrying infection up from the bladder must be considered. The other end is not always found and the catheter may penetrate the peritoneum with serious consequences. Yet in incomplete tears there are many cases where this simple procedure will reestablish the lumen of the organ, and restore the patient to health.

115 West Seventy-third Street.

TUBAL ABORTION

By Harry Cohen, M. D.,
New York.
Attending Surgeon, People's Hospital.

The subject of ectopic gestation has always been and, I suppose, will always continue to be of considerable interest. The ease with which the diagnosis is made in most cases, the pathognomonic signs and symptoms, the spectacular operation, especially in cases of rupture, and the low mortality, all appeal to the surgeon. To the patient and her family, an ectopic gestation confirmed by operation is a definite and comprehensible pathological entity, with its apparent dangers to life recognized. In this paper the etiology, symptomatology, history, etc., will be mentioned only briefly since these have already been described thoroughly by innumerable writers. Only such facts will be emphasized as I feel are important.

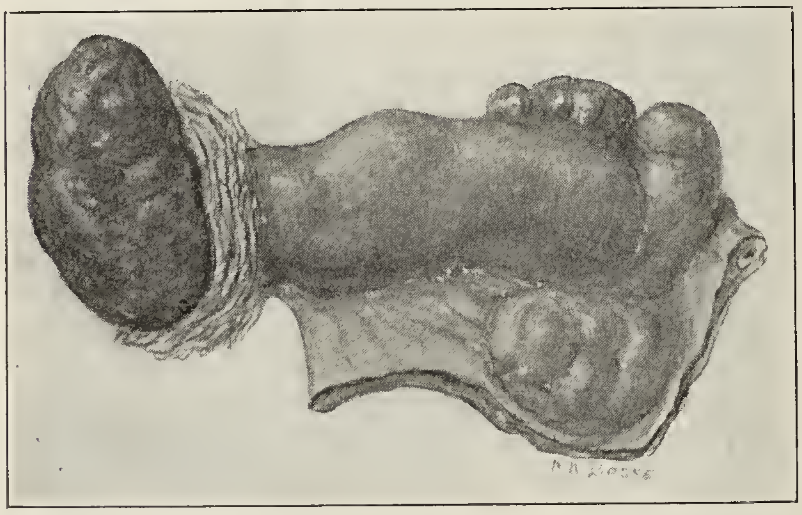

Fig. 1.—Tube whole with blood clot protruding from fimbrial end. (Case I.)

In the first place, I shall enumerate briefly the most important diagnostic signs. I can offer no improvement on those cited by Ladin (1) which are for the unruptured ectopic gestations:

1. Amenorrhea.
2. Subjective symptoms.
3. Pain caused by eroding cells in tubal pregnancy or to distention of the tube caused by the constantly growing ovum.
4. Uterine hemorrhage which is the result of decidual degeneration and separation.
5. Uterus somewhat enlarged.
6. Distended tube.
7. Two negative signs. a. No elevation of temperature. b. Exclusion of uterine pregnancy.

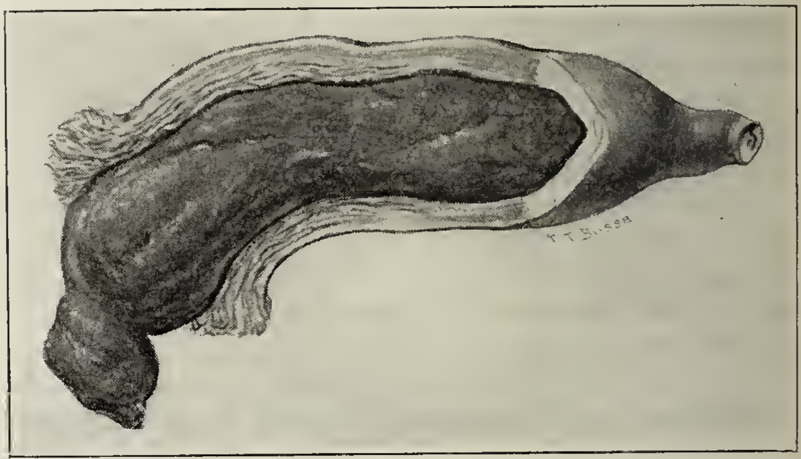

Fig. 2.—Tube with one side removed to show extent of clot which protrudes through fimbrial end. (Case II.)

In ruptured ectopic pregnancy, in addition to the signs mentioned above, there are also signs of hemorrhage, depending on the amount of bleeding, from slight syncope to shock and collapse. There is little that I can add to the etiology of ectopic pregnancy. Anything that will cause an incomplete obstruction in either tube can be the cause—salpingitis, adhesions, occasionally malpositions of the uterus, etc. In a case reported by Streeter (2) a subcutaneous implantation of the ovum was found which was caused apparently by a former modified Gilliam operation. This subcutaneous implantation of the ovum was an unusual form of tubal abortion. Gonorrhea has been blamed for many cases. Extrauterine pregnancy is not infrequently found in single girls.

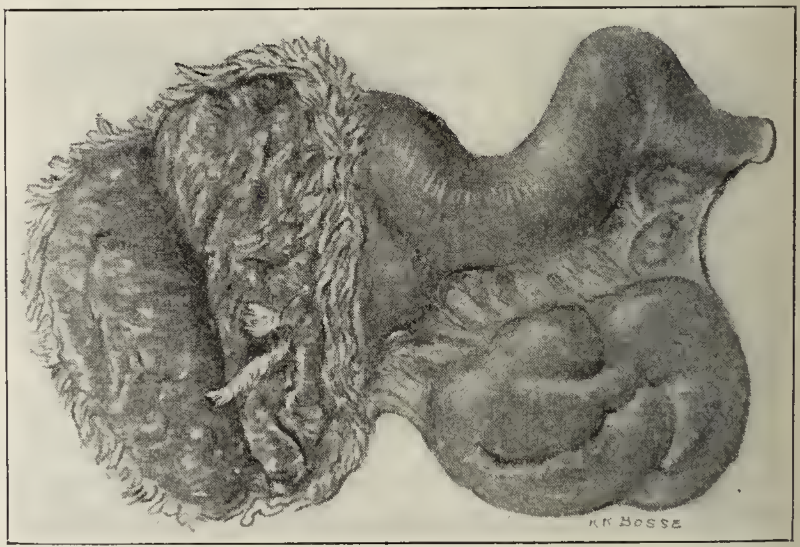

Fig. 3.—Tube with extruded mass walled off and adherent to fimbrial end. (Case III.)

The pathology, especially the gross pathology, presents an easy means of diagnosis. Caturani (3) found that of one hundred cases removed with the clinical diagnosis of tubal pregnancy only fifteen did not show positive microscopic evidence. On the other hand, the complete tubal abortion and hematosalpinx presented serious difficulty to the finding of evidence. His conclusions are that hematoceles are the result of ectopic gestation. It is a well known fact that most ectopics when they rupture do nothing more than abort through the fimbrial end of the tube. This happens in the majority of the cases. In only a small number do the tubes actually rupture. This tubal abortion may be so complete that, as cited by Caturani, no evidence of pregnancy may remain in the tube. Taylor (4) states that in a few cases of tubal abortion no operation was necessary. This is the explanation of the abdominal pregnancies of which many are on record. This brings us to the object of this paper which is to show by means of three specimens various stages of tubal abortion.

CASE I.—C. A., aged twenty years, married eight months, was admitted to the People's Hospital, November 1, 1919, with a history of one month's amenorrhea and two weeks' bleeding. Six hours before operation signs of tubal abortion developed with hemorrhage. At operation the abdomen was found to be filled with blood and the right tube presented the appearance of tubal abortion. The tube was only slightly enlarged. The patient gave birth to a normal child one year later.

CASE II.—A. B., aged twenty-eight, referred by Dr. J. Ruchman, was admitted to the People's Hospital on September 2, 1921, with signs and symptoms of a right sided ruptured ectopic pregnancy of approximately six weeks' duration. The patient had had two previous normal deliveries. On operation, the abdomen was found filled with blood and the right tube presented the appearance of a tubal abortion. The tube was considerably enlarged, and a clot was extruding through the tubal end. The clot, however, occupied the entire cavity of the tube, as was noticeable when the tube was cut open and part of the wall excised. In this case the ovary was not removed and therefore only the tube was seen.

CASE III.—M. M., aged twenty-six, referred by Dr. J. Philips, was admitted to the People's Hospital on March 25, 1919, with a history of two months' amenorrhea with subsequent signs and symptoms of a left ruptured ectopic gestation. At operation the tube was found considerably distended and the ovum had been expelled through the fimbrial end and was walled off and adherent to the tube.

Treatment of Gynecological Conditions by X Rays and Radium.—Robert Knox (*British Medical Journal,* October 14, 1922) shows that in serious cases it is always well to control the treatment by x rays and radium with blood counts at regular intervals so as to avoid accidents. A drop in the total number of white cells is always an indication that treatment must be suspended or continued cautiously; it is also a guide for the actual dose. In fibromyoma, for example, the contraindications for x ray treatment are: 1, calcareous degeneration of a large portion of the fibroid or if the tumor is large; 2, most forms of degenerations, but treatment may be tried if the degenerations are not extensive; 3, malignant disease of the uterus requires careful consideration; if the tumor cannot be removed, a combined attack with x rays and radium is indicated, and radium tubes should be applied carefully under general anesthesia; 4, complicating infective conditions of the uterus; 5, suppurative salpingitis or pelvic peritonitis; 6, inflammatory conditions of other organs in the vicinity, such as appendicitis, cystitis, etc., should be treated before treating a fibroid; 7, submucous pedunculated fibroids.

The advantages of x ray treatment are: 1, painlessness and ill effects of a temporary nature; 2, it does not interfere with the patient's ordinary habits of life; 3, no elaborate preparations are necessary; 4, the resulting menopause shows no such severe nervous disturbances as does operation; 5, recovery is rapid when the hemorrhage has been arrested and the shock from hysterectomy is avoided. The disadvantages are: 1, the long time necessary to obtain a result; 2, the treatment is not invariably successful; 3, the tumor does not disappear entirely; and 4, treatment may cause unfavorable changes in the blood. Indiscriminate treatment is dangerous, resulting in serious skin burns. The blood may be prejudicially affected by the larger doses in use at the present time. Overdoses to the deeper structures may give rise to serious disturbances of function at a later date.

Test of Labor.—W. G. Lee (*Surgery, Gynecology and Obstetrics,* July, 1922) from a study of one hundred consecutive deliveries concludes that no patient should be submitted to the test of labor in whom there are either obvious obstacles to pelvic delivery or emergency conditions necessitating speedy emptying of the uterus. The test of labor, therefore, primarily concerns cases in which spontaneous birth is hoped for, in the present and subsequent pregnancies. Operative delivery, when spontaneous birth does not ensue, should be by the pelvic route. Primiparity, posterior positions, dry labors, oligohydramnios, and constriction rings of the uterus, increase the percentage requiring operative delivery, particularly when they occur in combination. Constriction rings occur practically only where oligohydramnios or dry labor are present. Lack of progress for a considerable time is the predominant indication for interference. Occurring alone the determination of the moment for such interference demands careful consideration and wise judgment. Beginning maternal or fetal exhaustion, or threatened rupture of the uterus, developing with lack of progress, present indications for immediate interference. Any lack of progress, however, demands prompt, careful analysis to determine its probable cause with particular watchfulness for the development of such subsequent urgent indications for interference. Following a given test of labor, subsequent pregnancies should have an improved prognosis. Forceps will always be the most used method of terminating nonspontaneous labors; therefore, the technic of forceps operation is of paramount importance, and should receive greatly increased attention in obstetrical teaching.

Proceedings of Societies

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS AND ABDOMINAL SURGEONS

Thirty-fifth Annual Meeting, Held in Albany, N. Y., September 19, 20 *and* 21, 1922.

The President, Dr. Roland E. Skeel, of Los Angeles, Cal., in the Chair.

Tumors of the Breast.—Dr. John F. Erdmann, of New York, emphasized the belief that a growth in the remaining breast was as likely to be of primary origin as that in the breast first removed. Further, at the present day we were unable to state what the influence of x ray and radium was either as a preoperative or postoperative aid. But in view of many apparent reductions in size, etc., previous to operation in cases considered nonoperable, the use of x ray and radium should be encouraged. Even in view of some of the glowing reports at present regarding nonrecurrence, postoperative treatment should be substituted for preoperative, until some definite proof of its help or inefficiency had been established —since too few years had passed in his opinion for positive results to be shown. In the presence of late metastases the powerful currents of the present day should be given a thorough test to prove or disprove the efficiency of this method of treatment. The most thorough and painstaking wide removal, with remote glandular and fascial dissections would tend more and more to increase the percentage of cures and extension of life. The radical operation is attended with so low a mortality as to promote a greater desire on the part of the consulting physician to demand operation.

Genital Abnormality.—Dr. H. Wellington Yates, of Detroit, Mich., said that he had observed one case of abortion at about the sixth week in which there were a complete vaginal septum and a double uterus, except that the latter also had a septum between two otherwise normal uterine cavities. Complete vaginal absence was seldom found in any but nonviable monstrosities according to Anspach, but the case reported rather refuted this statement. Marked vaginal atresia might be the result of a vaginitis of gonorrheal origin, but complete congenital atresia was associated with anomalies in the development of the Müllerian duct and under those circumstances was always associated with abnormalities of the uterus and adnexa of one side. A true atresia of the vagina must be differentiated from the inflammatory type which was but the result of some acute infective agent.

Craniotomy.—Dr. A. M. Mendenhall, of Indianapolis, Ind., stated that craniotomy was an operation we should have no hesitancy in deciding upon in all cases where the child was dead and there were no insuperable obstacles to pelvic delivery of the mutilated child. Craniotomy upon a living child might at times be indicated if there existed little or no hope of its ultimate survival and the mother would be seriously jeopardized by any other method of delivery. The operation *per se* should carry with it no maternal mortality. With the safety of Cæsarean section in its various forms developed to where it was today, a craniotomy performed upon a living child always presented improper care either by the operator or his predecessors on the case.

Radium in the Treatment of Uterine Hemorrhage of Nonmalignant Type.—Dr. Edward A. Weiss, of Pittsburgh, Pa., said that in the treatment of benign hemorrhage from the uterus the following observations were to be considered: radium should be used only in selected cases such as myopathic bleeding of adolescence that did not respond to usual medical and hygienic measures; myomata with bleeding as a symptom that was of small or moderate size and uncomplicated by adnexal disease; menorrhagia of the menopause. The dose depends upon the age of the patient and upon whether the function of childbearing was to be preserved or sacrificed. Myomectomy in young women and hysterectomy when the tumor was large or complicated should be done rather than treatment with radium. Complications and unfavorable results are to be avoided only by a careful discriminating differential diagnosis. All cases treated by radium should be carefully followed up for several years.

The Cervix as a Focal Point of Infection With a Unique Case in Illustration.—Dr. Gordon K. Dickinson, of Jersey City, N. J., said that the cervix was a definite organ with a distinctive function. As a portal to the endometrium it allowed passage of nature's fluids. It also picked up bacteria, and carried them into the recesses of the mucosa, where they were either destroyed or became saprophytes. Harbored microbes might inflame the cervix and through the lymph stream cause more or less regional reaction, or, by the blood stream a varied expression. The cervix might act as a focal point for infections.

Uterine Displacements and Sterility.—Dr. Benjamin Rush McClellan, of Xenia, Ohio, stated that uterine malpositions were the cause of sterility in a limited number of cases, probably not over ten per cent, which, though small, was quite too large to be negligible. Long continued sterility or repeated abortions should make the gynecolgist suspect a displacement of the uterus. Malpositions acted as a cause of sterility by mechanically interfering with the progress of the spermatozoa into the uterine cavity and by contributing to the functional disability of the tubes and ovaries which, when long continued, resulted in organic degeneration, especially in the ovaries. In a few well selected cases a well placed pessary plus wisely directed hygienic and therapeutic remedies should be given a fair trial. Operative intervention was indicated in all cases where the foregoing treatment had failed, and where there was no legitimate contraindication.

Present Status of Surgery in Treatment of Fibromyomata Uteri.—Dr. Stephen E. Tracy, of Philadelphia, Pa., said that the status of any method was determined by the end results. To determine the best form of treatment for these neoplasms it was necessary to consider the degenerations in the tumors, the malignancies in the pelvic organs and the associate abdominopelvic pathology. Of all of the patients who consult a surgeon for symptom producing fibroids, thirty per cent had either degeneration of the tumor or malignancy of the pelvic organs. Abdominopelvic disease was found in forty per cent of the cases; seventy per cent of these patients had complicated tumors. In women past age of forty only sixteen to eighteen per cent. had simple uncomplicated tumors. It was impossible by any method of examination to determine which were simple uncomplicated tumors. The treatment of choice in the vast majority of cases was myomectomy for women under the age of forty years and hysterectomy in women past this age. This form of treatment removed all diseased tissue and relieved the patient of all symptoms in ninety-six to ninety-eight per cent of cases. Radium had a definite, though limited, field of usefulness in the treatment of these neoplasms. The use of radium should be restricted to small or medium size uncomplicated tumors at the menopausal period, to a patient with menorrhagia or metrorrhagia following myomectomy, and in certain constitutional diseases in which surgery would be attended with unusual risk.

Clinical Aspects of Blood Loss in Labor.—Dr. Paul T. Harper, of Albany, N. Y., stated that the intrauterine tamponade could be counted upon to check any postpartum hemorrhage, and such preparations should be made that it could be carried out without delay as soon as the more conventional methods demonstrated their inadequacy. Not only was it the most efficient method of active treatment of hemorrhage, but it was prophylactic as well, in that it made subsequent blood loss negligible. It expedited the convalescence from antepartum and intrapartum hemorrhage by making even physiological postpartum loss impossible.

Pituitrin in the Second Stage of Labor.—Dr. Magnus A. Tate, of Cincinnati, Ohio, said that from the literature at his command, where pituitrin was used in the second stage of labor, he found cases reported where the child was said to be asphyxiated, others where there was undue compression of the body of the child, cases of cerebral hemorrhage, separation of placenta, extensive lacerations of the cervix and rupture of the uterus. In some cases infants born alive became paralyzed and others became idiots and epileptics. He also found it stated that uterine tetany might occur following very small doses. He had used pituitrin in the second stage of labor for a number of years, and during the past year in thirty selected private cases, and had come to the conclusion that, if used judiciously, it was a boon to motherhood.

Malformations of the Uterus and Appendages.—Dr. Arthur T. Jones, of Providence, R. I., said that there were many varieties of malformations, most common of which were, 1, the uterus unicornis in which only one duct of Müller was developed. 2, the uterus bicornis in its various forms, in which both ducts were equally developed but there was fault in normal fusion and absorption. 3, uterus bicornis in which one duct was imperfectly developed and had no connection with the vagina. 4, the uterus didelphys in which the halves were separate throughout. 5, the uterus septus in which externally the uterus felt normal, but the partition between the middle portion of ducts of Müller had never absorbed. 6, uterus bipartus, in which both uterus and vagina were double and lay side by side as separate tubes. 7, double vagina in which fusion, absorption and development of the ducts of Müller were normal until the vagina was reached and here a partition was left, dividing the vagina throughout more or less of its length. In any of the above mentioned, pregnancy might take place. The conclusion he drew was a plea for conservatism and operations of a plastic nature to be resorted to rather than a complete removal of the female organs of regeneration. Uterine malformations should be watched for.

Transplantation of the Cervix.—Dr. W. Wayne Babcock, of Philadelphia, Pa., said that this operation was used in certain cases of sterility, anteflexion of the cervix, anteposition of the lower uterus segment, and for undue shortness of the anterior vaginal wall. In some cases the sutures were made to embrace the uterosacral ligaments so as better to hold the cervix up and back. In the first operation of this type which he performed about fifteen years ago for sterility of eleven years' duration, pregnancy quickly followed. The operation was simple, quickly performed and seemed to be of value.

Pernicious Effects of the Use of Stems in the Uterus.—Dr. J. N. West, of New York, states that in doing dilatation and curettage one should always wipe out the cervix with tincture of iodine so as not to carry the organisms which were found in the cervical canal into the body of the uterus and vaccinate them there with the curette. This applied to any other intrauterine instrumentation, except the use of forceps in delivery. He would advise against leaving the uterine packing more than thirty-six hours and then the use of iodoform gauze from which the iodoform had been washed by wringing out in water three or four times. Finally, the ideal surgical relief for dysmenorrhea, which was practically uniformly successful, was a thorough dilatation of the cervix and Emmet's amputation to a point one third of an inch below the internal os. This procedure had resulted uniformly in the relief of dysmenorrhea of anteflexion, and in many cases had relieved sterility.

What Is the Procedure in Cases of Dry Labor With Undilated Soft Parts, With a Study of the Relative Value of the Several Types of Section.—Dr. John Osborn Polak, of Brooklyn, stated that all cases of dry labor would fall within one of three classes. It must be admitted that each case of dry labor should be considered on its individual merits. The determining factors in selection of method were the position of the presenting part, the length of the labor and the condition of the cervix. Where infravaginal delivery was possible cervical dilatation was best handled with morphine and vaginal plugging, and finally, when section was elected, owing to the fact that all dry labors were potentially infected, the classical operation was not the one of choice, but one should be selected that excluded the peritoneal infection by peritoneal flaps.

(To be concluded.)

Abstracts from Current Literature

GYNECOLOGY AND OBSTETRICS.

Symptomatology of Displacements of the Uterus and Their Operative Treatment.—E. Schwarzenbach (*Schweizerische medizinische Wochenschrift,* October 12, 1922) asserts that the cause of the subjective symptoms in displacements of the uterus is always in the ligaments and that the circulation in the ligaments is often impaired in the operative correction of the displacement. The virginal displacements, as a rule, should not be treated; only when they have reached a severe degree after the onset of puberty, which is indicated by mechanical injuries corroborated by rectal findings, may subjective symptoms require treatment which should be operative, namely, fascial ventrofixation and not the Alexander-Adams operation. The retrodisplacements occurring in the puerperium should be corrected as soon as possible by treatment with a pessary for one half to three quarters of a year. Therefore. every woman should be examined to ascertain the position of her uterus about six weeks postpartum. If the retrodisplacement recurs, operation is indicated even before the symptoms develop; frequently the Alexander-Adams operation still suffices. If the patient decides in favor of an operation much later because of the severity of the symptoms, a fascial ventrofixation becomes necessary. Nonvirginal retrodisplacements, and those discovered after the puerperium, in which the time of origin is unknown and which produce no disturbance, should not be treated, regardless of whether they are fixed or not, except to cure sterility.

The operative treatment recommended is the following: The broad ligament should be spread out wide and lifted up, thereby bringing the uterus up into place and promoting the circulation in the ligaments. The uterus is held in place with a pedunculated strip of fascia from the anterior aponeurosis of the rectus muscle. It is sutured with silk to the anterior wall of uterus and the whole is covered over with the peritoneum. With this procedure, the root of the fascial flap is high enough so that the uterus can expand during a subsequent pregnancy without interference.

Atypical Epithelial Proliferations on the Uterine Cervix.—Fr. Chr. Geller (*Zentralblatt für Gynäkologie,* March 10, 1923) states that epithelial proliferations occasionally occur at the external uterine os, especially at the border between the pavement and cylindrical epithelium, which are difficult to characterize histologically, because even the most careful microscopic study fails to disclose their clinical dignity. The examination of three such cases revealed pavement epithelium at the suspected site and among it cervical tissue, which, however, showed changes in the cervical mucous membrane in so far as stratified or pavement epithelium was found under the specific epithelium and carcinomalike plugs proliferated into the depth, especially from the pavement epithelium. This pavement epithelium may originate from indifferent cells which remained from the fetal period between the cells of the cervix and which carried the ability to form pavement cells in themselves. These are epithelial proliferations, which originate from indifferent cells after a long period of latency, probably as a result of a disturbance of the normal relationship of the tissues to one another. They have been called cells with a disturbed internal balance. It is uncertain whether and when such proliferations come to a standstill. These cases should be repeatedly examined microscopically or at least be kept under continuous clinical observation.

Promontory Fixation in Prolapse of the Uterus.—Hans Hermann Schmid (*Zentralblatt für Gynäkologie,* March 10, 1923) lays stress upon the fact that the indications for promontory fixation of the uterus to a fixed bony point, for prolapse is far superior to the other operations for holding the uterus in its proper position, but that it can be used harmlessly only when the posterior lip of the cervix can be approximated to the promontory without tension. However, even under favorable conditions, there is always the danger of intestinal obstruction if the attached cervix becomes separated and a buckle forms between it and the promontory. This operation is indicated only in prolapse with a deep *cul de sac* of Douglas, when, for other reasons, a laparotomy must be done, in recurrent prolapse, and in prolapse of the vagina following extirpation of the uterus or supravaginal amputation.

Treatment of Eclampsia.—Thomas Watts Eden (*British Medical Journal,* October 14, 1922) bases his treatment of eclamsia on five points: 1. As it is easier to prevent eclampsia than to cure it, prophylaxis is all important. The premonitory symptoms of eclampsia should always be looked for. Prophylaxis requires rest in bed, fluid diet only (mostly water), saline purgatives, and diuretics. The salient points to watch are the amount of urine and albumin, the edema and the blood pressure. If progress is unsatisfactory, or if relapses occur after temporary improvement, labor should be induced immediately. All women who have at one time been on the verge of eclampsia should have labor induced, although it is well to wait until the symptoms have disappeared under treatment, if possible. 2. After a fit has occurred, prompt removal of the patient to the hospital is the first indication. The patient then requires a darkened quiet room, continuous supervision by at least two trained nurses, careful attention to the condition of the respiratory passages, plenty of fresh air with oxygen in reserve, and the continuous assistance of a clinical laboratory and expert medical superintendence. 3. A simple classification of cases as mild or severe according to, a, the amount of albumin in the urine (catheter), b, the number and frequency of the fits and c, the mental condition of the patient would greatly facilitate treatment. The severe cases are those with solidification of the urine on boiling, more than ten fits, and a continuous condition of coma. The mild cases are those with a moderate amount of albumin, few and infrequent fits, and a clear mind between the fits. 4. All cases of eclampsia are best treated by the minimum amount of obstetrical interference, limited to the induction of labor if it is not spontaneous and termination of the second stage of labor by low forceps when the head is on the perineum. Patients delivered either naturally, or by induction of labor, or by low forceps, show a much lower mortality than those delivered by rapid methods, such as accouchement forcé or Cæsarean section. The expectant obstetrical methods show the best results. Delivery by rapid dilatation of the cervix is unjustifiable and best avoided. Cases delivered by Cæsarean section show a mortality nearly double that of the similar cases delivered naturally or by simple obstetrical measures. 5. Simple medical treatment carefully regulated and constantly watched gives the best results. The methods of Stroganoff and Hastings Tweedy are simple in conception and detail. The general adoption of the principles advocated by these authors would result in an immediate reduction of mortality.

Calcium and Phosphorus Metabolism of Premature Infants.—B. Hamilton (*Acta Pœdiatrica,* July, 1922) concludes that the calcium retentions found in normal breast fed infants by previous investigators are insufficient to maintain the relative calcium content found in the body at birth. The calcium retention of premature infants may be small during the first two to four months of life, which fact, in combination with the rapid growth of these infants, must result in a more than normal decrease of the relative calcium content of the body, with resulting injury to the bone development. The phosphorus retentions of normal infants have been found to be larger than the retentions of calcium during the first three months of life. The prematurely born infants retained phosphorus in nearly normal amount in many cases. The calcium retentions of the prematures were, as a rule, of normal magnitude only in those cases where the intake exceeded one fifth of a gram of calcium oxide daily. This fact seems to indicate that the calcium minimum of these infants is of about the same magnitude as that of infants born at full term, and that the demands of the internal metabolism are of greater moment than the demands of the growing bones. When the calcium intake is less than one fifth of a gram of calcium oxide daily, the intake is for the most part, it seems, absorbed by the internal metabolism, and only a small amount is available for retention.

Tuberculosis and Pregnancy.—Heinrich Pehan (*Wiener klinische Wochenschrift,* October 5, 1922) concludes as follows: 1. Tuberculous affections that have run their course and those that are not progressive afford no indication for the artificial interruption of pregnancy. 2. Pregnancy, labor and the puerperium cannot induce a flaring up and further advance of an existing tuberculous affection; in such cases, the artificial interruption of pregnancy may be taken into consideration after a prolonged observation of the patient, but this must be fortified by physical examination, röntgenography and control of the body weight and temperature. 3. The outlook of success is dependent upon the severity of the disease and the duration of the pregnancy; the interruption of the pregnancy up to the beginning of the fourth lunar month and the first stage of tuberculosis (Turban classification) affords the most favorable results, but nevertheless these cases should be judged prognostically by their anatomical character. The complication of laryngeal tuberculosis is an indication for the interruption of pregnancy in the early months. 4. The interruption of pregnancy in the second half of the term, the particularly in the last lunar months, is no less dangerous than at birth at the normal period.

Prenatal Hygiene and Problems of Maternity and Child Welfare.—W. M. Feldman (*British Journal of Children's Diseases,* October-December, 1922) states that prenuptial clinics should be established where persons of both sexes can get expert advice in regard to their fitness to marry. No person knowingly suffering from syphilis should be allowed to marry and the breach of such a rule should be made a penal offense. Every person who has at any time been exposed to the risk of contagion by venereal diseases should be declared free from both syphilis and gonorrhea before marriage. All cases of prenatal syphilis should be thoroughly supervised and treated as soon as diagnosed. All expectant mothers should, as far as possible, refrain from alcohol (at any rate to excess) or excessive smoking throughout pregnancy. All expectant mothers should be protected from exposure to infectious diseases or dangerous industries, such as lead and phosphorus, or tobacco factories. Attention to teeth, bowels and kidney functions is of great importance during pregnancy. The relative size of the fetus and maternal pelvis should be carefully watched and any abnormal presentation should be converted into a vertex before labor. Antenatal wards or beds should be provided in connection with all antenatal clinics for the purpose of treating abnormalities of pregnancy, as well as for the purpose of carrying out properly directed and well coordinated biochemical, pathological and statistical research.

Intranatal Deaths.—Eardsley Holland (*British Medical Journal,* September 30, 1922) asserts that at postmortem examinations, fifty-one per cent. of fetal deaths may be traced to the complications of labor, as shown by the presence of cerebral or visceral hemorrhages. The tentorium cerebelli was found torn in half the cases and in eighty-eight per cent. of dead fetuses after normal breech delivery. In the light of such evidence, the teaching that the delivery of the aftercoming head must be hurried for fear of pressure on the cord must be revised, inasmuch as the fetus is actually killed by compression of the head, principally due to forcible efforts to complete the extraction of the child: the head may be allowed as much as ten minutes, if necessary, for delivery.

Malignant Chorioepitheliomata.—Theodor Nagy (*Gyógyászat,* July 3, 1921) in explaining the development of chorioepitheliomata says that the most difficult point of explanation is the transformation of the epithelium and villi of the chorion into malignant tumor cells. The embedding of the ovum in the uterine wall and the establishment of intercommunicating material and fetal circulation through the mechanism of the villi and uterine vessels are well known. However, a more particular knowledge of the process is still lacking, to determine whether maternal blood colloids pass through the placental vessel walls, thus, by means of the maternal albumin, building up the embryo, or whether those colloids must first undergo a process of assimilation. Investigations have shown that frequently villi of the chorion are carried away into the different organs of the mother. It is not so long ago that eclampsia was explained on this basis. But postmortem examinations have shown that these miscarried villi, or such as have degenerated into moles, are not necessarily transformed into chorioepitheliomata. Many factors may play the etiological rôle in encouraging and accelerating the development of these new growths, which are more malignant than sarcoma. Sometimes, while the primary focus shows no symptoms, metastases occur to such an extent as to obscure the primary site of the disease. It is also possible for the original focus to disappear before the patient consults the clinician.

Results of Radiotherapy in Cancer of the Uterus.—W. S. Flatau (*Zentralblatt für Gynäkologie,* May 12, 1923) finds that if the irradiation treatment is extended into several series over a long period of time, many patients, for some reason or other, do not return for treatment. He therefore believes in an intensified form of treatment with irradiation, and advances the following requirements: 1, the greatest possible homogenization and hardening of the ray cone; 2, irradiation of the entire pelvis (uterus, ligaments, lymph tracts, lymph nodes and connective tissue) through a single field; and 3, simultaneously or immediately preceding or immediately subsequent combination of excentrically applied and concentrically active distant röntgenization and concentrically applied and excentrically active radium treatment. The author uses fifty mg. of radium within the cervix for forty-eight hours; fifty mg. of radium in the vagina for twenty-four hours; and immediately preceding or immediately subsequent to this treatment he applies irradiation to the entire pelvis by means of four distant fields, one dorsal, one ventral and two lateral. In twenty-two operable cases, seventeen patients are living and in forty-six inoperable cases, twelve patients are living. For röntgen intoxication the author advises the administration of a teaspoonful of sodium chloride immediately after the irradiation.

Standardized Dose Method of Using Scopolamine Morphine During Labor.—N. Hirschman (*British Medical Journal,* October 14, 1922) finds that it is the morphine that causes the analgesic effect in the mother primarily and allows the scopolamine to take effect. A second dose of morphine is not necessary, but if for some reason or other it does become necessary, the physician should make sure that the child will not be born in the danger period, namely, from two to three and a half hours after the last injection of morphine, as a child born at that time is very oligopneic. A smaller dose of morphine—for example, heroine one twelfth grain—although producing less amnesia or analgesia in the mother, will not cause this oligopnea. The danger period can be avoided by combining 1/150 grain atropine with the initial injection of morphine scopolamine. On the whole, the author obtained his best results in primiparæ and multiparæ with an initial dose of morphine one quarter grain, scopolamine one one hundredth grain, and atropine one one hundred and fiftieth grain, followed by one four hundredth grain of scopolamine hourly. Instead of one quarter grain morphine, the author thinks one half or two thirds grain omnopon would be better. The initial dose of morphine should be from heroine one twelfth grain to omnopon two thirds grain, depending on how long labor is expected to last. A nurse, experienced with the twilight sleep technic, should be in constant attendance. This treatment is particularly indicated in primiparæ and in cases where a lengthy severe labor might be expected. It also saves the doctor much trouble and allows him to attend to his other duties. Chloroform should be given only at the end of the second stage, not only for obstetrical reasons but also because it prevents "islets of memory" or impressions on the brain. With ordinary reasonable care, there need be no untoward effects on the mother, and little, if any, on the child.

Maintenance of Obstetrical Anesthesia by Means of Infundibulin and Chloroform.—A. F. Martin (*British Medical Journal,* October 14, 1922) states that the parturient woman, being peculiarly amenable to the action of chloroform, can be rendered amnesic by maintaining a light partial anesthesia, which is harmless to mother and child, if the uterus is kept active by means of repeated small doses of infundibulin. Usually 0.5 c. c. of infundibulin every half hour or so is enough, the chloroform being administered with the onset of and during the pains. A Junker inhaler is a valuable help in avoiding the use of too much chloroform and in regulating the dose. The amount used will vary, the author having achieved a satisfactory amnesia with a minimum dose of three drams every hour.

Lumbar Puncture in the Treatment of Eclampsia.—Th. Heynemann (*Zentralblatt für Gynäkologie,* February 3, 1923) says that lumbar puncture has been discontinued in eclampsia, in which disease it was formerly frequently used, becomes the base of the brain and the cauda equina might be pushed downward owing to the increased intercerebellar pressure. The author reports several cases in which he was enabled to achieve a rapid improvement or elimination of the brain symptoms with the aid of lumbar puncture. Inasmuch as he is one of those who believe that eclampsia is due to disturbances in metabolism, he naturally does not consider the lumbar puncture as etiological therapy, and consequently he considers it to be indicated only after venesection and delivery of the child have failed and, particularly, when cerebral symptoms, such as convulsions and disturbances in vision, exist. Lumbar puncture should be done with the patient lying down.

Lesser Cæsarean Section.—Heinrich Doerfler (*Zentralblatt für Gynäkologie,* February 10, 1923) calls the interruption of pregnancy and sterilization done at one time "lesser Cæsarean section." He opens the uterus with a transverse incision immediately above the cervix, which he covers later with the vesicouterine fold and then removes the fetus with the finger and the amniotic membrane and remains of the placenta with a dry compress. He does not cut the tubes for the purpose of sterilization, but sterilizes in a bloodless manner, by lifting the tube up, piercing the resulting fold of mesosalpinx several times with silk, throwing a sling around the elevated tubal portion, and knotting the tubal coil with the thread. He then draws the ligated tubal coil into the mesosalpinx and buries it there. As a result, that portion of the tube which is tied off degenerates. In this way the dangers of the ordinary induction of abortion and the subsequent second operation of sterilization are diminished. The operation at one sitting is a great boon to the patient.

The Socalled Preliminary Irradiation Treatment of Carcinoma of the Cervix Uteri and Subsequent Operation.—A. Mayer (*Zentralblatt für Gynäkologie,* October 7, 1922) for a long time has treated carcinoma of the cervix uteri with considerable success according to the following plan: Only in those cases showing no ichorous purulent discharge were the patients operated upon immediately; in those cases showing such a discharge the patients were irradiated first and operated upon only after the discharge had disappeared. In sixty-seven cases treated according to this plan (radiated first and then operated upon, ten; operated upon immediately, fifty-seven), the primary total mortality was 7.4 per cent (as compared with 20.3 per cent formerly) and the mortality from peritonitis was 4.4 per cent (formerly 10.9 per cent), thus showing the justification for preliminary irradiation.

A Clinical Study of Cancer of the Uterine Cervix.—James W. Ross (*Canadian Medical Association Journal,* November, 1922) says that in very early cases of cancer of the uterine cervix treatment by surgery alone gives good results; surgery in combination with radium gives slightly better results than surgery alone. In operable but not early cases treatment by surgery alone or combined with radium gives the best results. Radium alone and the Percy cautery alone are of equal value and both less efficient. In cases considered inoperable because of extension to the vagina surgery gives the best results and radium is disappointing. In inoperable cases radium, alone or in combination with cautery or surgery, is the only effective agent. In advanced cases radium is superior to all other methods, but is not curative. The incidence of fistula is higher with the Percy cautery than with any other method.

Solid Carcinoma of Ovary.—M. R. Hoon (*Annals of Surgery,* December, 1922) offers the following conclusions: Solid carcinoma of the ovary may occur at any period of life from childhood to senility, the most common period being in the fourth and fifth decades. The tumors are highly malignant and are more often primary than the recent literature indicates. Solid carcinoma of the ovary may be bilateral, but in sixty-six per cent of the cases the tumor was unilateral. Melanotic carcinoma is occasionally primary in the ovary, and is highly malignant, as is the same type of tumor elsewhere. The general history is similar to that of ovarian fibroma, with the additional symptoms of malignancy, loss in weight, strength, and appetite, and secondary anemia. The growth of the tumor is usually rapid. Ascites cannot be considered a criterion of malignancy, as it was present in thirty-five per cent of the solid carcinomata and in twenty-five per cent of the benign fibromata. The treatment of solid carcinoma of the ovary is surgical removal followed by röntgen ray and radium, if total removal of malignant tissue is impossible. Metastasis and local recurrence indicate a hopeless prognosis, but palliative treatment may be given by radium and the röntgen ray.

Mixed Tumors of the Uterus.—A. J. Petersen (*Journal of Laboratory and Clinical Medicine,* March, 1923) adds to the recorded cases of mixed tumor of the uterus two instances. In the first case the sections of the tumor showed bone, hyaline cartilage, smooth muscle, white fibrous connective tissue, and alveoli of round and spindle cells. The patient died three months ofter operation with recurrence of the tumor in the pelvis (one year after the appearance of symptoms). The second tumor showed cartilage and smooth muscle fibres, fibrous tissue, but the greatest proportion of the tissue was areolar tissue. The patient was living and well two years after operation and six years after the appearance of symptoms.

Pathology of Fetal Maceration.—Gilbert L. Strachan (*British Medical Journal,* July 15, 1922) draws the following conclusions from a study of twenty-four cases: 1. Maceration is the result of the retention of a dead fetus *in utero,* the particular cause being an insignificant factor. 2. Maceration alone is no indication of the existence of syphilis. 3. The examination of the placenta is absolutely necessary. 4. The bony changes in the macerated fetus superficially resemble the chondroepiphysitis of syphilis and this condition must be carefully differentiated. 5. The microscopical examination reveals a process of autolysis of the constituent cells of the various organs with edema of the interstitial tissue and an extrusion of red blood cells. 6. In syphilitic cases, the placenta is thick and pale, whereas nonsyphilitic often show hemorrhages and infarctions.

Febrile Abortion.—Hermann Steichele (*Zentralblatt für Gynäkologie,* September 21, 1922) is in favor of assuming a middle position between radical and conservative treatment in cases of febrile abortion. Every case of febrile abortion is at first let alone, but if hemorrhage occurs as a result of the placental remains not being expelled completely, the uterus should be evacuated as gently as possible with a forceps and a dull curette. In the presence of peritonitic symptoms and suspicion of a perforating injury, every attempt at evacuation of the uterus should be avoided.

Metabolism in Pregnancy.—E. J. Cornell (*Surgery, Gynecology and Obstetrics,* January, 1923) asserts that from the findings in this series of cases the following conclusions may be reached: There is an increase in the metabolic rate above normal in pregnant women. It has a wide variation, however; there is nothing approaching a constant. The test is subject to many errors beyond the control of the technician. The mental attitude of pregnant women is not stable, therefore the readings are not always reliable. Many tests in the experiment were not included in the report because of the hysterical condition of the patient at one or both tests. The results in toxic cases were so variable that no reliable information was obtained. We could lay down no rule to guide us in determining the degree of toxicity or recovery in a given case. Neither could we say from the reading that labor should or should not be induced. The death of the fetus cannot be predicted from the metabolic rate. The test consumes considerable time, effort, expense, and patience far out of proportion to the value of the information obtained.

Albuminuria in Pregnancy.—Aleck W. Bourne (*Practitioner,* September, 1922) submits the patient to medical treatment for four days, of which starvation for the first twenty-four hours plays a prominent part. Should there be no improvement in any of the symptoms on the fourth day, he thinks it wise to induce labor without further delay. Many patients show a decided improvement, and they may be allowed to progress a little further in pregnancy should the child's interests demand a further period *in utero,* but should the child have reached a development of thirty-eight weeks labor should be induced after a few days of detoxication. If a toxemic patient exhibits any one symptom in a pronounced degree, such as excessive edema, a blood pressure above 190 m m., or albuminuria of two per cent. or over, labor should be induced after not more than two days of medical treatment. Some symptoms, such as uncontrollable vomiting in late pregnancy and jaundice, are especially dangerous and indicate immediate termination of the pregnancy. A sudden exacerbation of a symptom already present, or the appearance of a fresh symptom, during medical treatment, demands the immediate induction of labor. Finally if there is doubt about the diagnosis of true toxemia or chronic nephritis and pregnancy, the pregnancy should, in most cases, be ended at once. In a patient who is going to do well the headache and edema subside coincidentally with an increase in the quantity of urine and a reduction in its specific gravity. The amount of albumin usually diminishes, but seldom disappears until after delivery. The diminution of albumin to a faint cloud is a good sign but does not signify that the patient is out of danger. The blood pressure usually falls a little in twenty-four hours, if the patient is in bed and undergoing depletive treatment, but is slow in subsiding to normal. It usually remains above normal for a fortnight after delivery and the disappearance of all other symptoms.

Treatment of Atonic Hemorrhages in Cæsarean Section.—W. Sigwart (*Zentralblatt für Gynäkologie,* November 18, 1922) states that hot irrigations, the Momburg belt, or the Sehrt clamp are available for atonic hemorrhages if the birth takes place through the natural passages, but in a laparotomy these procedures are applicable only with great difficulty. On the basis of his observation that the introduction of anesthesia ether into the laparotomized abdomen produces intestinal peristalsis, the author poured about fifty c. c. of ether into the uterus in several cases of atonic bleeding in Cæsarean section. The result was a stony hard contraction of the uterus. Simple rubbing of the external surface of the uterus with gauze wipes soaked in ether was also effective and more advantageous than the usual massage of the uterus. The special advantages of this procedure are the simultaneous disinfecting effect and the diminished hemorrhage with subsequent excision of the angle of the tube.

The Kielland Forceps in Obstetrics.—Rudolf Stiglbauer (*Wiener klinische Wochenschrift,* October 19, 1922) states that the advantages of the Kielland forceps are the following: 1, the straight form of the spoon, with only a slight curvature of its edges, by means of which the head of the fetus may be grasped transversely by avoiding its application in an oblique diameter; 2, the gliding lock, which allows the fitting of both blades in any position without the application of force; and 3, the slight width of the forceps at the junction of the spoon and the handle, whereby every millimetre of unnecessary distention of the soft parts is avoided. It is a vast improvement over all the models of forceps in use heretofore; its manipulation is easy and it spares both mother and child any unnecessary injury.

Experiences With the Kielland Forceps.—E. Neumann (*Zentralblatt für Gynäkologie,* February 3, 1923) reports on his experiences with the Kielland forceps, which are of particular interest because nearly all of the patients showed a contracted or flat pelvis, the head being up high or impacted in the pelvis and not rotated. With few exceptions, the anterior and posterior spoons could be introduced immediately, anteriorly and posteriorly; only once was elevation of the posterior spoon past the promontory difficult and once the anterior spoon could only be turned in the uterus. The introduction of the spoon in the transverse diameter, as with the classical forceps, and allowing it to accommodate itself, is not so easy. The typical application of this forceps usually causes no difficulties. The rotation of the head by 90° or 135° is almost always exceedingly easy, provided the forceps is properly applied. A slipping of the forceps is possible only with a faulty application. High forceps extraction in a narrow pelvis may be done with little force. The Kielland forceps is, therefore, highly recommended both when the head lies up high and also as a rotation instrument and also as a substitute for the Naegeli forceps in typical operations, not only in normal, but even in contracted and occasionally in flat pelves. However, the Kielland forceps should never be used by the general practitioner, but only by the specialist.

The Etiology of Gout

By R. LLEWELLYN JONES LLEWELLYN, M.B. (Lond.),
London,
Member of the Conference (Medical Research Council) on Arthritis and Allied Rheumatoid Conditions.

It was with many misgivings that I acquiesced in the suggestion that I should open a discussion on gout—that riddle of the ages—the elucidation of whose etiology has vexed the minds of all thoughtful physicians from time immemorial. For our forefathers were well aware of the profundity of the problem.

"A knowledge of the real nature of gout is, in my opinion, at the very foundation of all sound pathology," said Tod, many years since, and the passing years have but invested his reflection with deeper significance and something of prophetic insight.

For, who can doubt that he who would unravel the pathological groundwork of gout, must be at once a clinical physician, a biochemist, a bacteriologist, a morbid anatomist, and well may we ask, who is sufficient for all of this?

It is with chastening reflections such as these that we may best approach that vexed question—the etiology of gout. For though our knowledge of the chemical structure of uric acid, and its allies, has of late vastly increased, nevertheless we are far from the solution of the pathological mystery of gout.

HEREDITY.

Now as to the etiology, both intrinsic and extrinsic agencies are involved. Of the intrinsic the most salient is heredity, and as Fuller aptly says, "From father to son, its seeds are transmitted, and bear fruit in exact proportion to the degree in which circumstances prove favorable to their growth."

That gout is hereditary is beyond question, but whether purely so, or capable also of acquisition *de novo,* is uncertain. Certainly of all arthritic diseases, gout furnishes by far the most instances in which parents and children are alike victimized.

Thus Garrod, Ooberts, and Luff in private patients found an ancestral taint in from seventy-five to eighty-one per cent. Albeit they maintain that gout can be acquired *de novo*. Personally I find it difficult to appreciate their attitude. They insist on innate or static proclivities in gout, and in the same breath are equally insistent that it may be acquired *de novo*. As to the evidence adduced, it is negative rather than positive, based mainly on failure to establish any ancestral tendency.

But seeing that they elicited an hereditary influence in three fourths or more of their cases, is it not probable that the same taint—though apparently undiscoverable—was at work in the residual fourth? Is not this more likely than that in their particular instance the disease was newly and wholly acquired?

Personally I believe the alleged acquisition *de novo* of gout to be apparent rather than real. My own opinion is that the predisposition thereto is always inherited, and that the factors we presume may originate gout, are merely evocative, not causative. In other words, the primary or essential cause of gout is an inborn morbid tissue potentiality, in the absence of which the alleged predisposing or exciting causes are impotent to evoke the disorder.

Apart from statistics how otherwise can we explain the fact that of a large number of persons given to precisely those alcoholic and dietetic excesses that we presume may create the disorder, not one may develop gout, while others who lead literally "A godly, sober, and righteous life" are veritable martyrs thereto. How escape then the conviction that in gout "breed is stronger than pasture"?

It is not gout, of course, but the predisposition thereto that is inherited. Moreover, the morbid potentiality lies latent, unless evoked. Thus females of gouty stock, infinitely more often than not, escape overt gout, but hand on nevertheless their inborn liability to their offspring. Seeing then that gout may lie dormant for a generation, is it surprising that in some cases, admittedly a minority, the family history proves sterile?

Again, the presumption that gout is purely hereditary gathers weight when we recall that its metabolic eccentricities relate to nuclein rather than protein metabolism. For, it is in nuclear changes that we may best discern the initiation of oxidation processes and other varieties of enzymatic activity. Moreover, as Walker Hall points out, "The presence of masked iron, phosphorus, and certain forms of fat in the cell nucleus strengthens this view, and thus we are

Copyright, 1923, by A. R. Elliott Publishing Company.

led to recognize the important part played by the nucleus in the life of the cell, and to appreciate the influence of nuclein heredity in cellular exchanges."

Again, turning to the end product of nuclein metabolism—uric acid—do not its anomalies of excretion and deposition also seem to predicate inherited nuclear peculiarities, with their correlated perversions of function? That such constitute the pathological groundwork of gout is, I think, further indicated by the fact that socalled gouty inflammation—in virtue of its associated uratic deposition—is *sui generis.* No tissues, other than the gouty, react in this specific fashion. Does not this seem to indicate that the soil—the inborn tissue peculiarities—dictate, so to speak, the character of the pathological reaction? This indifferently, whatever the nature of the socalled predisposing causes which—if my assumption be correct—do but evoke or make manifest what is already latent.

Assuming that gout be purely hereditary, what is the nature of the morbid potentiality transmitted? Some define it as an inborn defect or alteration of protein or nucleoprotein metabolism. But, pending more exact knowledge, I would by preference ascribe it to inherent instability thereof. Instability predicates excessive or abnormal response to normal stimuli, and judged clinically this is the salient characteristic of the gouty, in a word, hypersensitiveness. How otherwise explain their manifold idiosyncrasies in respect of foodstuffs, alcoholic fluids, drugs, etc.?

Nowadays persons who exhibit idiosyncrasies towards foodstuffs, etc., are regarded as anaphylactic thereto. But be this as it may, much of the recent research on anaphylaxis centres around asthma, a disorder whose kinship with gout is traditional. In the matter of heredity, they are very reminiscent one of the other. Thus the son of a gouty parent, happily warned by the excesses of his father, may remain immune, while in turn his son, forgetful of his evil heritage, may bring it again to fruition. In like fashion a father, though himself free from asthma, may transmit to his children the tendency to protein sensitization, bequeathed him by his forbears.

Now protein sensitization being, so to speak, the live link in asthmatic heredity, is it not highly probable that the hereditary transference of gout also connotes the transmission of a tendency to nucleoprotein or rather protein sensitization. I say protein, because researches show that any antigenic properties that nucleoproteins possess are referable to their protein and not their nuclein moiety. For apparently purified nucleins are not antigens, at least not in the ordinary sense. For none of their constituents, nucleic acid or other, seem to possess antigenic properties.

I would then suggest that the live link in gouty, as in asthmatic heredity, is the transmission of a tendency to protein sensitization. I have the less diffidence in that more often than not, gout develops on a soil already sensitized, as betokened by the fruit already borne in the shape of asthma, urticarial and eczematous eruptions, or some one or other of the toxic idiopathies. These we know to be due to protein sensitization, and when we recall how frequently these precede articular gout and alternate therewith, is it not highly probable that arthritic gout is but another clinical variant thereof?

The suggestion gathers weight when we recall the many clinical analogies between gout and asthma. Thus both disorders are paroxysmal and periodical, prone, moreover, to clinical interaction and alternation, and their victims notably given to idiosyncratic reactions. The resemblance goes even deeper, for de Kleijn and von Leeuwin have recently noted that bronchial asthmatics exhibit the same disturbances of purin metabolism met with in gout, viz., retention and delayed excretion of exogenous purins. Moreover Czerny, Paltauf, and others assert that the children of gouty stock are especially liable to a symptom complex marked by asthma, cyclical vomiting, vasomotor ataxia, and eosinophilia. The asthma may alternate with urticaria and eczema, and moreover as Uffenheimer emphasizes, these children again display the same disabilities of purin excretion as their gouty parents.

FOOD IDIOSYNCRASIES.

I would remind you in this connection that Duckworth long since observed that the food idiosyncrasies of the gouty often began in early life, and with the passing years might die out and be replaced by other idiosyncrasies. Moreover, the *pari passu,* their liability to certain disorders showed a like periodicity. Recent studies on protein sensitization strikingly confirm these observations.

The sensitiveness which in infancy finds expression in eczema may later be exchanged for sensitiveness that manifests itself in asthma, and as I think myself, may later still in life take the form of regular gout. For, if it is true that many cases of asthma beginning in early life, date from the suppression of an eruption, it is equally true that an asthmatic paroxysm has vanished with the onset of frank gout, and that thereafter the gout has alternated with asthma or with eczema, or with urticaria. Herein may lie the explanation of the hitherto inexplicable interplay of regular and socalled irregular or abarticular manifestations of gout. In other words, that these various disorders superficially so dissimilar, are but multiple expressions of one species of morbid action.

The food idiosyncrasies of the gouty are proverbial, not eclipsed even by the asthmatic. Some appear hypersensitive to beef, others to pork or veal, some to shell fish, others to certain vegetables or fruit, e. g., strawberries. The almost fulminant swiftness of the response in some instances frankly suggests that the gouty outbreak is due to the absorption of unaltered protein, and moreover, the digestive derangement of the gouty would seem to favor the intrusion of unaltered protein or cleavage products.

Here I would protest against the belief that the idiosyncrasies of the gouty relate chiefly, if not entirely, to nuclein rich foods. Sweetbreads, it is true, in some evoke outbreaks, but others take them with immunity. In short, the response of the gouty to a purin free diet is undeniably erratic, which is not surprising, seeing that it was based on the assumption that uric acid was the *fons et origo mali* in gout.

It is asserted that it reduces the degree of uricemia, and therefore the attacks of gout. But variations in the degree of uricemia occur independently of diet, and acute outbreaks ensue, even when as the result of atophan the uric acid blood content is subnormal.

Apart from these discrepancies the prime drawback of the purin free diet is, that it does not exert a direct or specific influence on the *causa causans* of gout, but only upon the results thereof. For we now realize that the uricemia and uratic deposits are but symptomatic of gout—the outcropping, so to speak—of some more profound metabolic disturbance.

But if so, then to what may the variability in response of the gouty, not only to a purin free, but to all other standardized diets be ascribed? The reason, if I may suggest, is that—indifferently whether the diet be rich or poor in nucleoproteins—t is not the nuclein, but the protein moiety thereof that is the disturbing element, the responsible antigen.

In other words, the salient point is, not whether he diet be purin free or what not, but does in either or any instance contain the specific protein or proeins to which the particular gouty individual is hypersensitive. Only on this more catholic basis can we hope to cope with the food idiosyncrasies of the gouty, which extend far beyond nuclein rich foods.

Thus, for example, strawberries being purin free, are admitted to a purin free diet. Yet it is notorious that some gouty, like some asthmatic subjects, are hypersensitive thereto, developing urticaria or frank gout. Nevertheless many gouty persons, like Linnaeus, eat them with impunity. The inference then s that some gouty persons are hypersensitive to the particular protein in strawberries, others not.

If this be true of strawberries, what of the proteins in other purin free substances? For turning to the elements of a purin free diet, we find them rich in those proteins that evoke asthmatic paroxysms, viz., wheaten bread, milk, eggs, rice, etc. Now if so in asthma, why not in gout? The question seems more relevant when we recall that bronchial asthmatics are subject to the same disabilities of purin excretion as the gouty. Indeed for this same reason de Kleijn and von Leeuwin placed their asthmatics on a purin free diet. Here again, as in gout, the results were conflicting, some benefitted, others not.

Unfortunately those who proved obdurate were not subjected to protein skin tests. But, judging from other workers' findings, they would have been found hypersensitive to wheat, or other proteins. The same reasoning I submit would explain the erratic response of the gouty to a purin free diet, viz., in those who benefit the protein to which they are hypersensitive has unwittingly been abstracted. Conversely, in those who do badly, there remains an unguessed at sensitization to cereal or other proteins.

I would suggest, then, that the food idiosyncrasies of the gouty, are due to protein sensitization, and hat the disturbances in nuclear metabolism are secondary thereto. I have less diffidence since experimental researches show that purin free proteins, viz., glidine, markedly stimulate nuclear metabolism with ncreased output of endogenous uric acid. Moreover, the same follows ingestion of the end products of protein digestion, e. g., the amino acids, i. e., alanine, and glycocoll, also the bicarboxylic amino acids, i. e., glutaminic and aspartic acids.

This fact that purin free proteins or their derivatives markedly intensify nuclein metabolism furnishes, I think, a clue to the food idosyncrasies of the gouty. Incidentally, the increased nuclear catabolism might account for the tendency to uricemia—the degree of which has possibly some bearing on that more salient feature of gout—uratic deposition.

Again, not only do the most diverse proteins apparently evoke gout, but wholly alien substances, such as lead, exposure to x rays, and last but not least, infections. Surely nothing could more clearly demonstrate the abnormal or specific instability of the gouty. Be it food, drink, lead, or what not, every gouty man has his own peculiar antigen or antigens.

Moreover, as to diet, if it is to be more satisfactory, we must take cognizance of more than nuclein rich foods. In truth, our attitude must be at once more catholic and infinitely more eclectic. Our net must be wider spread, but its mesh exceeding small. For in gout, as in asthma, every man is a law unto himself.

Passing to alcoholic fluids, Sir Clifford Allbutt in a recent contribution on gout observes, "Let us protest against the equivocal use of the word 'alcohol' when we mean wines or ales. There is no evidence," he adds, "that alcohol does more harm to the gouty than it does to other people. We are all better without spirits."

Le Gendre also holds that alcohol *per se* cannot originate gout, but probably that something in wines or beers has eluded us, some associated substance. Now, if we cannot impeach the alcohol, then to what other constituent can we refer the gout evoking properties of malt liquors and wines as opposed to distilled spirits?

The elder Garrod long since observed that "Neither the acid nor the sugar, nor any known principle in wines or malt liquors, can as yet be proved to impart to the alcohol its predisposing influence. For wines the least acid, and liquors the least sweet, are among the most baneful."

Now, comparing malt liquors with wines one difference emerges. Malt liquors contain purins, while wines are held purin free. Yet both are equally provocative of gout. Albeit, we know that nucleic acid, the mother substance of purins, has no antigenic properties.

Is it then a question of personal idiosyncrasy? Apparently so, for of the multitude of beer drinkers, but a tithe have gout. Moreover, even in gouty subjects, beer does not infallibly evoke an outbreak. Sydenham, indeed, advocated mild beer, and Burney Yeo insisted that some gouty subjects drank stout with impunity. Obviously then, it is essentially a question of personal idosyncrasy. In other words, those beer drinkers—relatively few—who do have gout, are sensitized or hypersensitive to something in the beer other than its alcohol or purins. To what then are they hypersensitive?

I suggest, to the proteins in beer, viz., to hordein, or some other protein in malt. I single out hordein for—like glidine and other vegetable proteins—it produces a typical anaphylactic reaction. Another possible source of sensitization might be the protein material in yeast cells, for dry yeast contains fifty per cent. of nitrogenous substances, proteins, peptones, etc.

Passing the wines, these like malt liquors are the product of fermentation, produced spontaneously by the yeast cells always present in the grape. The saccharomyces ellipsoideus is the type of yeast responsible. Of this there are many species or races, only to be differentiated physiologically. This allows of varieties of yeast proteins being concerned in the maturation of different wines.

Now, though in the course of racking, yeast cells subside to the bottom of the cask, nevertheless, Julius Wortmann elicited this fact. He examined a large number of old wines, and invariably when the wine was still in good condition, he found living yeast cells always present.

Now, seeing that the varying characters of individual wines admittedly depend largely on the particular yeast concerned, may we not here find a clue to the erratic response of the gouty to this or that wine? In other words, why some can stand champagne, others port, and yet both come to grief on the reputed more innocuous claret or hock.

If living yeast cells are always present, even in old wines in good condition, is it not possible that those who manifest gout after their consumption are hypersensitive to one or other of the proteins contained in the different races of yeast cells? Apart from this, we know that in the process of fining wine, protein substances are actually added, in white wines such well established antigens as casein and skimmed milk. In contrast, red wines are often treated with white of egg. I suggest then that the wine idiosyncrasies of the gouty are due to protein sensitization, either to proteins developed during fermentation of the grape must, or added subsequently in the process of fining.

OCCUPATION.

In persons who are predisposed, exposure to lead may evoke gout, and this by several routes. It may follow its ingestion in medicinal doses. Again, it has ensued through the inhalation of snuff taken from lead packages, or it may be the result of absorption via the skin or mucous surfaces. Munro saw an initial outbreak occur within two days of resort to a hair wash containing lead. Now, if a metallic poison like lead can by its inhalation or absorption evoke gout, why should not the proteins of barley or other cereals in some instances act in like fashion?

I say so having been struck with the fact that—apart from those directly concerned with brewing and malting—gout develops with significant frequency in those whose work involves the mere handling of grain. Judging from statistics, gout is as common among coachmen, grooms, stablemen, and farm laborers as in draymen, maltsters, brewers' laborers, and so forth.

Now it is a strange thing if we meet with gout in a lead worker, we impeach the lead and not the beer which he may and often does drink. On the other hand, if we meet with gout in a maltster or drayman, it is ever and always the beer he drinks. But not all publicans are sinners. Moreover, we admit that the lead worker may acquire his gout by inhalation or absorption through skin or mucous membrane. Then why discount the possibility that the drayman or ostler may acquire his gout also by more innocent routes than the alimentary canal.

Again, Wilson Fox long since noted that some persons, when exposed to lead fumes, developed not gout but asthma, and so we have this same metal lead, evoking in one individual gout, and in another asthma. Now, cereal proteins we know may by inhalation or absorption in some persons induce asthma, then why should they not, in other instances, like lead, evoke gout, and this by direct contact?

It seems not so improbable when we recall that the proteins of strawberries may in one evoke gout, in another asthma. But to my point, as to the possibility of sensitization by these alternative routes in the brewing trade. Barley is, of course, the cereal usually employed, and the technic of malting, grinding etc., is such that the hordein, or other proteins contained in the malt dust, might sensitize by direct contact. Again, the brewers' yeast or saccharomyces cerevisciæ—multiplying as it does by spore formation—might do the same. For the spores of yeast, like the ethereal pollen, are readily diffused by air currents.

Now we admit that sensitization with resultant asthma is especially prone to ensue when, as in millers or others, the protein comes into direct contact with the conjunctival, nasal, or respiratory membrane.

Is it not possible then that the socalled gouty throat is the outcome of sensitization by direct contact of the proteins in malt dust or yeast spores? If so, it would readily explain why a socalled gouty tonsillitis or pharyngitis, or according to many, a conjunctivitis or episcleral congestion so frequently and immediately precedes a classical outbreak.

I would suggest then that the predominant incidence of gout in the occupations mentioned above is that those in whom the disorder develops are sensitized. Moreover, that such sensitization may be but is not necessarily the outcome of the ingestion of beer. But, that being in the course of their work, exposed to the corresponding protein or antigen, sensitization, as in asthma, may occur by the alternative routes of inhalation or absorption of the proteins of malt dust, in brewing or malting, or of the proteins in crushed oats, wheat, etc., in stable and agricultural work.

For some deep etiological significance, I feel sure, attaches to the fact that not only do these two conditions, gout and asthma, so frequently overlap clinically, but that the trades also in which they predominantly occur should alike be concerned with the handling of cereal grains or other manufactured products.

Lastly, there is some evidence that even such widely divergent substances as lead and proteins act after a somewhat similar fashion. For though nonproteins like lead may not sensitize, it is suggested that they may combine with or alter the proteins of an animal so that they become as foreign proteins to that animal and so cause sensitization.

TRAUMA.

Fractures, dislocations, and surgical operations have very frequently determined gouty outbreaks. Now, our experience of war casualties suggests that in extensive traumatisms the products of tissue autolysis may engender grave intoxications, or conditions sometimes interpreted as shock. Researches on animal anaphylaxis seem to show that it is especially the slightly altered proteins, possibly only changed in their colloidal properties, that are most probably responsible.

But apart from extensive traumatisms, even trivial shocks such as extraction of a tooth, or vaccination, have determined outbreaks. In one case under Munro and myself, the initial attack occurred between two injections of typhoid vaccine. Unfortunately I have neither seen nor read of any instances in which gouty patients have exhibited extreme hypersensitiveness towards horse serum.

Lastly, in olden days leeching in gout was common. But it was found to lead to fresh outbreaks, and so abandoned. Is it not possible that the outbreaks were due to sensitization to a foreign protein derived from the leech? Such, too, might be the explanation of Heberden's classical instance, where he said he verily believed the attack had been excited by a gnat bite.

MENTAL STRAIN OR SHOCK.

The potency of mental strain or shock in evoking gout is historical, but its modus operandi obscure, but in the light of Pavlov's researches, there is no doubt as to the inhibition of gastric secretions by unpleasant psychic stimuli. In view of this it would seem probable that sudden mental shock or prolonged anxiety through the sequential gastric derangements might favor the intrusion of unaltered proteins or cleavage products, and in this way cause sensitization.

INFLUENCE OF SEASONS.

The tendency of gout to occur almost exclusively in the spring has been known since the days of Hippocrates. Its predilection for this period is difficult to explain, but I would remind you of Hamilton's researches on louping-ill or chorea paralytica as it occurs in sheep. It is a disease of the spring, and Hamilton noted that during springtime the blood of sheep affords an excellent culture medium for the responsible bacillus. At other seasons the blood is not only inimical to its growth, but intensely bacteriolytic thereto.

Is it not possible, also, that in man the protective mechanisms of the blood are lessened at particular seasons, so that the growth of pathogenic organisms in associated local foci, is in some subtle way favored. In other words, that microbes lying dormant in such foci become active, with the result that the cells of their host become sensitized to their proteins. For, to my mind, it is highly probable that sensitization to bacterial proteins is gradually developed in chronic infections, such as pyorrhea, etc., and this occurs more commonly in gouty than in normal persons.

THE INFLUENCE OF INFECTIONS.

It has long been recognized that a great number of disorders which we now know to be infective, frequently determine gouty paroxysms. Numerous instances, said Garrod, arising from boils and carbuncles have come under my notice. Moreover, modern observers all agree as to the frequency of local infective foci in gouty subjects. Lastly, the general features of acute classical gout, its paroxysmal nature, and periodicity, strongly suggest the intrusion of an infective element.

But even those who hold infection responsible for the arthritic phenomena, find it difficult on this basis, to account for the socalled irregular or abarticular manifestations of gout. But the difficulties seem minimized, if we take the view that focal infections evoke gout through the medium of anaphylaxis.

In other words, that the articular and abarticular phenomena of gout are due not to the direct action of toxins generated by organisms in some local focus, but that they are the outcome of an anaphylactic reaction to the proteins of the said organism.

Reflections on the anaphylactic symptom complex —reinforced by some peculiarities in socalled gouty arthritis, have led me to this conclusion. The salient features of anaphylaxis, as Dale has shown, are spasm or tonus of unstriped muscle, e. g., the bronchioles, and poisoning of the endothelial cells of the blood capillaries. Moreover, one or other of these effects may predominate in different species of animals, and thus give rise to symptoms which, though superficially dissimilar, are yet fundamentally due to the same species of morbid action.

That they are due to one common type of poisoning, is, in Dale's opinion, further confirmed in that these same symptom complexes may be produced by a whole group of natural poisons—partial cleavage products of proteins formed by bacterial or other ferments.

In like fashion in man—under natural conditions of life—there may occur that particular sequence of events essential for the artificial induction of animal anaphylaxis; in other words, an entry into the blood of unaltered or incompletely digested proteins—a definite interval—then a second entry with resulting explosion. When such occurs, the salient features of anaphylaxis are reproduced, and find clinical expression in asthma, skin eruptions, arthropathies, vascular hypotension, and eosinophilia. In some individuals urticaria, in others bronchial asthma, or arthropathies, may be the predominant manifestation.

Now, when we reflect on the varied clinical phenomena of serum sickness or anaphylaxis in man, they seem very reminiscent of gout, in its regular and irregular aspects. Thus, in both we have joint swellings, asthma, skin eruptions, and I think, the resemblance extends even to the vascular hypotension and eosinophilia.

The prevailing impression, I believe, is that in gout the blood pressure is raised, but I am sure there are many exceptions. Thus, Sir Clifford Allbutt recently observed. "Time after time, so far as palpation can go, I have found the accessible arteries, even of elderly persons, long liable to acute or chronic gout, soft to the touch, and the blood pressure moderate. I am disposed to say that on the whole the subjects of frank gout are not more liable to atherosclerosis than other persons of equal age."

As to eosinophilia, Neusser many years ago held it to be a feature of the blood changes in gout. More recently, Bain in a case of acute gouty polyarthritis noted a marked increase of eosinophilia, and Munro, in some cases of my own, observed a similar tendency thereto.

IRREGULAR MANIFESTATIONS OF GOUT.

Now, I may remind you that many of the currently regarded irregular manifestations of gout are frankly relegated to the group of toxic idiopathies, notably asthma, urticaria, and edema, also some types of gastrointestinal disturbance.

Now, if the irregular manifestations of gout are rightly so included, why not its regular or articular phenomena? For classical articular gout, to my mind, represents the very acme of idiosyncratic response, if only by reason of this salient fact that no other articular disorder is associated with uratic deposition. That we should exclude regular or articular gout from the toxic idiopathies is the more remarkable in that arthropathies are among the most common features of the anaphylactic symptom complex as portrayed in serum sickness. Moreover, it is generally held that the joint pains and swellings of serum sickness, like the urticarial and edematous lesions, are due to poisoning of the capillary endothelium. Hence, presumably the reason why they are generally referred to as arthropathies rather than arthrites; and I believe that in like fashion the joint swellings of gout would be more fittingly described as arthropathies than as arthritides.

For acute classical gout displays peculiarities which sharply contrast with the usual phenomena of arthritis. Thus, no form of arthritis is so definitely paroxysmal and periodical. Certainly none that repeatedly runs so definite and fixed a course, without subsequent adhesions. Again, in most forms of arthritis, the motor phenomena, muscular wasting, predominate. But in gout, sensory disturbances are to the fore, i. e., pain and perverted sensations. Lastly, it stands unique in virtue of the associated uratic depositions.

PREMONITORY SYMPTOMS OF GOUT.

Turning to the elements of a typical fit in the toe, I would first allude to the premonitory symptoms exhibited in the limb about to be attacked. These take the form of painful muscular cramps, sensations of coldness, or numbness along the limb, and objectively, engorgement of the veins not only of the foot, but of the leg, where the same marked turgescence is visible. If it be the hand that is attacked, this same preliminary engorgement of the veins of the arm is to be noted.

Now, the character of these symptoms distinctly suggests that the primary morbid change in oncoming gout is a disturbance of the circulation. The more so, seeing that in authentic instances urticarial or erythematous eruptions are sometimes superadded to these prodromata—these same vanishing with the onset of the attack as signalized by pain.

Now, for a few hours after its onset there is no outward change in the periarticular region, only the venous turgescence. Then the parts become red and swollen. The redness reaches its acme in about thirty hours, but the surrounding edema goes on slowly increasing for some four or five days. The vivid scarlet glazed appearance—suggesting pus where none is—later fades into violet, and with the passing of the fit the edema subsides, the cuticle peels, with subsequent itching and numbness of the foot that persists for some days.

Here are surely many anomalies difficult to reconcile with the orthodox evolution of an arthritis. But there are still further anomalies. Thus, the excruciating pain of gout has this peculiarity first noted by Sydenham. It may be conjoined with a feeling of icy coldness in the joint, or in contrast, a sensation of boiling heat. But the degree of pain and its subjective character seem independent of the local phenomena as estimated by redness, swelling, and local heat. Indeed, as Scudamore first noted, one of the cardinal signs of inflammation, calor or local heat is often if not always lacking in gout. Duckworth too, judging by the thermometer, noted that the local temperature of the joints involved in acute gout, is commonly lower than that simultaneously taken in the axilla or mouth, sometimes by five or six degrees.

The body temperature, too, displays remarkable vagaries. In socalled asthenic gout, though the joint be red and swollen, and the disease runs its usual course with subsequent desquamation, yet the temperature throughout is normal.

This incongruity is even more strikingly exhibited in acute gouty polyarthritis, where three or four of the larger joints may be painful, red, and swollen, and yet the temperature be normal. As Osler says, "A patient with three or four joints red, swollen and painful in acute rheumatism has fever, and while pyrexia may be present, and often is in gout, its absence is, I think, a valuable diagnostic sign."

To sum up, are we not here confronted with a series of events whose character and sequence is—even apart from the associated uratic deposition—specific or *sui generis*. I say so advisedly, for the subject of articular gout is not immune from other forms of arthritis. He often has acute rheumatism in early life, and at a later age, manifests acute gout, and either before or after this, he may have suffered from acute gonococcal arthritis.

Nevertheless, these alien joint disorders—despite the gouty soil—remain true to type. This shows that the joints of a gouty man—when exposed to the direct action of microbes or their toxins—do not necessarily or invariably respond with a uratic arthritis.

The inference, then, to my mind, is that for the production of a true gouty or uratic arthritis, there is required not only a specific gouty soil, but an equally specific mode of pathogeny. In other words, that a socalled gouty arthritis is not—as in gonococcal or other types—due to the direct action of microbes or their toxins, but is achieved indirectly, through the medium of some special morbid mechanism.

For myself, I believe that the initial change in acute gout is a toxic poisoning of the endothelium of the vessels and capillaries in the joint area. I note that Dale, discussing the action of histamine, holds that it embodies the main features of a reaction which, if it occurred locally would be construed as a mild inflammation. In continuance, he observes, the widening of capillary lumina, the opening up of channels, ordinarily empty, the transudation of plasma through abnormally permeable endothelium, and the tendency to stasis of the concentrated blood—these phenomena, when occurring in an area so restricted that the general arterial pressure is not materially affected, will produce the familiar sequence of redness, swelling, and edema.

Now, according to Dale, the foregoing circulatory changes are the outcome of vasoconstriction of the arterioles combined with vasodilatation of the capillaries and venules. As a result, we get obstruction to the inflow of arterial blood, and therewith stasis in the venules and capillaries.

Now, applying these to the elucidation of acute gout in the toe, we find a ready explanation of the premonitory symptoms, the coldness, numbness, muscular cramps, and venous turgescence, viz., that they are due to restricted arterial supply and venous stasis. Moreover, these occurring in a localized area such as the toe, we get the familiar redness, swelling, and edema.

The pain too is explicable as due to local ischemia, as likewise the subjective coldness, and absence of local heat, while presumably the subsequent desquamation, itching, and local numbness, would admit of a like explanation. Clinically, the supposition of circulatory stasis seems reasonable, when we recall that actual thrombosis of the veins leading from the affected part has indeed been noted during the actual progress of a paroxysm.

URATIC DEPOSITS IN GOUT.

Now, as to the associated uratic deposits. Even in gouty subjects there is as far as we know, no interference with the orderly sequence of enzymatic reactions eventuating in uric acid. But here comes the flaw—the uric acid when formed fails of transport and elimination. It is precipitated and anchored in the tissues, and I note that Sir Clifford Allbutt holds that uratic deposits never occur in sound tissues, cartilage or other. They are only laid down in the connective tissue substitutes. This being so, he maintains that inflammation, however slow and inactive, must be assumed as a condition precedent to uratic deposits.

Now, I have suggested that the local blood supply of tissues the seat of acute gout is reduced. A reduced blood supply results in increased H ion concentration. This greatly favors autolysis, which ensues chiefly if not solely in asphyxiated tissues. I would suggest then, that as a result of local ischemia the cartilage undergoes anemic necrosis, with secondary uratic deposition in the connective tissue laid down in its place.

Wells states that during autolysis the intracellular enzymes attack the protein group of the nucleoproteins, setting free the nucleic acids. These in turn, are disrupted by the specific enzymes nuclease, liberating the purin bases which again undergo further disruption. May it not be then that the uratic deposits are due to the inadequate removal of the substances resulting from these local nuclear activities, and that the relatively high sodium content of cartilage, determines the incidence of uratic deposits therein?

Moreover, as serum inhibits the action of the intracellular autolytic enzymes, it follows that with restoration of the free circulation, the tissue autolysis ceases.

CONCLUSIONS.

In attempting to summarize my views on this vast subject—the etiology of gout—I would remind you that Dale holds that sensitization—in anaphylaxis—is cellular and not humoral in location. In other words, that in vascular endothelial poisoning, the anaphylactic symptoms are not due to collision of the antigen and antibody in the blood stream. For his researches show that the antibody is located in the cell, and that it is there in the cell body itself, that the reaction with the corresponding protein or antigen occurs. Hence the anaphylactic symptoms—possibly the result of intracellular precipitation.

On this basis the pathological groundwork of gout resides in a tendency to cellular sensitization. The same may remain latent, but once established it will —given contact with the related protein or antigen— at any moment explode. The explosion takes the form of vascular endothelial poisoning, and as the same operates through the medium of local ischemia and venous stasis, it is not surprising that the clinical manifestations thereof should be extremely diverse. For, the symptoms will naturally vary with the regional distribution of the circulatory stasis, and the structure and function of the organ or tissue implicated.

If situated in a joint, it results in regular gout, if in the lung, asthma, if in the skin, urticaria, or eczematous eruptions, viz., irregular gout. Accordingly, if we accept cellular sensitization as the basal pathological change in gout, and that the same achieves its malign effects, through vascular endothelial poisoning, we seem to glimpse the inward meaning of the clinical mosaic presented by the regular and irregular manifestations of gout.

Incidentally, too, much of the mystery attaching to gouty metastases disappears, even the much maligned retrocedent gout becomes intelligible. Thus, if an acute gout in the toe suddenly abort, and alarming gastric symptoms as suddenly ensue, viz., intense abdominal pain, collapse, vomiting, sometimes of blood, may not these gastric symptoms be due to a local endothelial poisoning, a gastrostasis?

Conversely, in those authentic instances where an aphasia, an amnesia, or a hemiplegia, disappears with the onset of frank gout, may not the cerebral symptoms be due to temporary stasis in the related cortical vessels.

Again, may we not find herein a facile and no less a rational solution of those many recorded examples in which a fleeting erythemata or urticaria has, like a bout of asthma, vanished with the sudden outbreak of acute classical gout; or alternated therewith in that dramatic fashion so graphically portrayed by the older physicians, to whose masterly clinical insight, modern research ever brings increasing tribute.

Lastly, it seems to me that this conception of the etiology of gout opens up an encouraging vista for more efficient, and I would fain add, more scientific therapy. May not skin protein tests, if applied to the gouty, yield as rich a harvest of information as has already been gleaned in asthma? May not withdrawal of the offending protein, whether vegetable, animal, or bacterial, prove as prophylactic in the one as in the other? May not our sheet anchor—colchicine—even act as a desensitizer? But time and discretion alike forbid that I wander further in the regions of speculation.

May I then suggest the following points for discussion:

1. Gout is purely hereditary.
2. A tendency to cellular sensitization is the pathological groundwork of the disorder, viz., latent gout.
3. The gout is evoked by the corresponding protein or antigen, whether animal, vegetable, bacterial, or other.
4. It exerts its effects through the medium of vascular endothelial poisoning, with muscle tonus, especially of the bronchioles.
5. The same finds its clinical expression in the regular and socalled irregular manifestations of gout, viz., arthropathies, eczema, urticaria, asthma, etc.

Tuberculosis Among the North American Indians

Review of the Report of a Committee of the National Tuberculosis Association, Appointed on October 28, 1921

By S. ADOLPHUS KNOPF, M.D.,
New York.

To the average citizen of the United States the North American Indian is a vanishing race, and I am sorry to say that there are some men selfishly interested, claiming to be Americans, who wish for the disappearance of the Red Man. Let me however say to those who think that the North American Indian is doomed to disappear, that there are a number of Indian tribes now who are prosperous, increase in numbers, and constitute a desirable asset to our population. We know that there are quite a number of distinguished men and women who proudly trace their ancestry to some of our Indian tribes. One of them was my late, good friend and universally esteemed coworker, the late Dr. H. B. Favill, of Chicago. He was a most active and enthusiastic pioneer in the antituberculosis crusade and one of the prime movers and founders of the Chicago Tuberculosis Institute. He was deeply interested in the cause of the consumptive poor, a man of unusual professional ability, a gentleman and scholar, and to know him was to love him. Of fine features and of typical Indian stature, he made a striking appearance. Favill was of course also interested in the Indian problem and in the terrific death rate from tuberculosis existing at that time among many of the Indian tribes. But in the early days of the National Tuberculosis Association it was not strong and powerful as it is today and was obliged to concentrate its efforts mainly upon the prevention and treatment of the consumptive poor among the white population.

The prevalence of tuberculosis among our North American Indians, which in some tribes is increasing, has naturally been the concern for a number of years of all interested in this splendid race. After a number of state organizations, such as the Nebraska and Oklahoma associations, had interested themselves in the tuberculosis problem among the Indians, Dr. Kober, realizing that it was a problem concerning all the Indians of the United States, recommended the appointment of a committee by the National Association to study the problem thoroughly and make such recommendations as, with the cooperation of the United States Government, will better the existing conditions and, if possible, tend toward the eradication of tuberculosis among the Indian population. This committee was appointed October 28, 1921, and at the completion of its labors published their findings and recommendations.

HISTORICAL DATA.

Until the admirable report of this committee under the chairmanship of Dr. George M. Kober of Washington appeared no authentic information, covering all the Indian tribes on this subject, was available, and we owe a debt of gratitude to Dr. Kober and his coworkers for the careful study they gave to this important problem. The historical data, that is to say, the bibliographical researches on this subject, begin with a quotation from *Jesuit Relations* (Thwaite's edition, VI, p. 263) 1633. Among the interesting historical items relating to the subject is the mention of Benjamin Rush's work *Free Thoughts Upon the Cause and Cure of Pulmonary Consumption* (1794), in which he says: "Pulmonary consumption is unknown among the American Indians." However, J. D. Hunter, in the *American Medical Recorder* of 1823, modifies this assertion by saying: "I have known pulmonary consumption to occur among the Indians. It is rarely seen, however, except in those who are addicted to intemperance, and even in these it is by no means so common as among the whites."

PERSONAL OBSERVATIONS.

Very interesting are Dr. Kober's personal observations made during his army service from 1874 to 1894, when he came in contact with different Indian tribes. He was stationed at Camp McDermitt, Nev., from November, 1874, to July, 1877, where he observed the Paiutes. He subsequently came in contact with the Nez Perces, Spokane, and Klamath Indians, remaining with them until 1880, when again he came in touch with the Paiutes, near Fort Bidwell, in northeastern California. He does not recall a single case of pulmonary tuberculosis among them until after 1884, and then only among Indians who had exchanged their tepees for badly constructed and unsanitary dwellings. After this he observed cases of pulmonary tuberculosis among adult Indians, and also a case of tuberculous meningitis in a girl aged ten. It is Dr. Kober's belief that the Indians in Modoc County probably did not contract the disease from the white race, since during his entire practice, 1880-1894, covering 4,097 square miles, and with a population of about five thousand, he had only seen two cases of pulmonary tuberculosis among the settlers. As a matter of fact, the first white settler arrived after 1865. It had often occurred to him that the introduction of cattle by the whites may have played a rôle in the spread of the disease. In this connection it should be mentioned that between 1874-1877 the scarcity of food compelled the Indians near Camp McDermitt, Nev., to consume the flesh of domestic animals that had died. This same habit he found to exist among the Paiutes and Modocs in northern California from 1880-1894, and it appears to have prevailed elsewhere. While bovine tuberculosis is extremely rare among the range cattle of northern Oregon and California, it is not infrequent among milch cows.

The last item of historical interest mentioned is by Dr. Matthews who gave to the American Climatological Association, in 1888, the results of his twenty years observation in a dozen different states and territories and came to the following conclusions: "We have evidence that the wildest Indians in the earliest historic times were subject to consumption, yet they were not subject to it in a high degree, and it is probable that they suffered then from a different form of the malady to that which troubles the modern Indian. We have evidence that scrofula begins to prevail among them when they cease to live by chase, and that it (scrofula) is a condition predisposing to consumption among them."

INCREASED MORTALITY FROM TUBERCULOSIS AMONG INDIANS.

The records of later years, however, show an alarming increase in tuberculosis among the Indians. Thus we read in Col. Bushnell's latest book on *The Epidemiology of Tuberculosis*: "Several hundred Apache Indians (Chief Geronimo's Band), among whom were comprised some women and children, were confined at Mount Vernon Barracks, Ala., in 1887. According to the report of the Surgeon General for 1896, the death rate in the first year, 1887-88, was 54.64 per 1,000, and during the second year, 48.96, but it run up during the third and fourth years to 109.69 and 142.84, nearly one half of which was due to tuberculous disease. At this time great improvement was made in their condition; a new village was built for them, and they were placed under the most vigilant sanitary supervision, with the result of bringing the death rate in 1891-92 down to 109.75, the next year to 80.93, and in 1893-94 to 98.36. The prisoners were transferred to Fort Sill, Okla., in October, 1894, the excessive mortality that had prevailed among them in Alabama being one of the chief reasons for effecting the transfer. Here they were asisgned land and led a free life. At the end of the first year at Fort Sill it is reported that their condition was much improved, but that the death rate continued high, 83.05 per 1,000; yet it was thought that a large part of the mortality was referable to infection at Mount Vernon Barracks. Of the total of twenty-five deaths, seventeen were due to tuberculous disease. Glandular affections were common among these Indians, but the deaths were chiefly due to pulmonary tuberculosis."

MORTALITY RATE AMONG INDIANS IN THE UNITED STATES ARMY.

The report then describes the mortality rate among the Indians in the U. S. Army, which concludes with the significant statement that the rates of admission, discharges and deaths of Indians from pulmonary tuberculosis are enormously greater than those of the other troops. Most striking is Dr. Matthew's conclusion concerning the Cherokees, in which he says: "In view of all the evidence now before us, we may declare that some of the highest rates of mortality from consumption and other tuberculous diseases among Indians are found in communities which have been longest in contact with civilization."

May I be permitted to add here that this increased death rate is not because of contact with the best environments which civilization has created, but with the worst, otherwise the socalled susceptibility of the Indian and the colored race as well might well be considered a negligible matter. The committee arrived at almost the same conclusions when it makes the following statement: "Those of us who have seen the Indians in the wild state, and admired their splendid physique and wonderful power of endurance, can not believe that such a race is destined to become extinct by reason of a peculiar susceptibility to tuberculosis. While it is true that the Indians, like the African race, have shown a nonresistance to the disease producing causes which are afloat, the real cause is not inherent but due to the fact that they have been the victims of most unfavorable environments in the transition stage of their civilization."

Dr. Kober's vast experience in dealing with the tuberculosis problem among the Negroes of the District of Columbia also shows that pure water and air, condemnation of dwellings unfit for human habitation, the erection of sanitary homes at reasonable rental, pure food laws with special reference to milk, registration of tuberculous cases, and care and treatment in suitable hospitals, legislation and education for the prevention of contact infection, infant and child welfare work, better economic conditions, and a more plentiful and suitable supply of food, were responsible for the reduction of the general death rate among the Negroes of Washington, D. C., from 1,102 per 100,000 in 1875 to 265 in 1921.

CAUSES OF INCREASED PREVALENCE OF TUBERCULOSIS AMONG INDIANS.

Surveys by special investigation commissions in 1904 and a survey conducted by the U. S. Public Health Service in 1912 in the twenty-two States which have Indian reservations, are reported and the following conclusions arrived at: The main cause of the increasing prevalence of tuberculosis among the Indians may be ascribed to overcrowding. There is a high birth rate among the Indians. It is no unusual sight to see eight or ten individuals living in one small dwelling, or for Indian families to huddle together, even in commodious quarters.

It would lead too far in this review to reproduce the 178 interesting answers which were received from Federal agencies and from thirty-nine State agencies of the Bureau of Indian affairs. The questions asked were the following:

1. Have you statistics which indicate an increase or decrease in the spread of tuberculosis among the Indians?

2. What, in your opinion, are the most prominent predisposing causes in the spread of tuberculosis among the Indians?

3. What methods have been adopted by the Federal and State authorities and State and local tuberculosis associations to diminish the spread of the disease among the Indians?

4. What remedial action would you recommend for the alleviation of existing conditions?

From the conclusions of the inquiry, I will only quote the most striking ones: "Scrofula and consumption were observed among the Indians of North America as early as 1635. . . . No bones of undoubtedly pre-Columbian origin have been found that show tuberculous lesions, and such lesions are very rare in Indian bones, dating from the period of the earliest contact with the whites. . . . From the available data, it is also evident that there has been a progressive increase in the prevalence of the disease since their contact with the whites. . . . Some tribes were thoroughly tubercularized, while others showed the characteristics of a recent acquaintance with the disease in its high fatality. In most of the Indian tribes it would probably be correct to say that tubercularization was progressing but was as yet not complete. . . . In view of these facts and in the light of our knowledge concerning the influence of environments, food, and economic conditions on the rise and fall of tuberculosis in some of the Indian tribes and among the American Negroes, some observers hesitate to accept the conclusion that the American Indian was especially susceptible because of a lack of previous exposure. Those who are familiar with the tuberculosis movement, especially in the Central European states during the World War, are deeply impressed with the fact that lack of food both in quantity and quality, worry, anxiety, chronic fatigue, and undermined health are important factors in the reactivation and ravages of the disease. In the consideration of the question of susceptibility of the Indian to tuberculosis, we should bear in mind that the advent of the white race was promptly followed by a struggle for existence and subsistence. One of the baneful effects among the inland Indians was a gradual destruction and dispersion of their game and other natural sources of food supply, causing extreme suffering and a state of semistarvation."

RECOMMENDATIONS OF COMMITTEE.

Among the recommendations which the committee offers as the result of its labors, are primarily of course sanatoria where the adult Indian in the last stage of tuberculosis can finish his days without jeopardizing the lives of those to whose care he is committed. Public health nurses to instruct in the care of the sick and in the prevention of the disease, and prenatal and infant welfare work. A better compensation for all fulltime salaried medical officers, teachers and employees in the Indian service, sanitary inspection and the removal of all unsanitary conditions, proper supervision of the food and water supplies, and a well balanced diet in the institutions and homes. The pasteurization or simple scalding of the milk for all classes, but especially for infants and children is strongly urged, as well as the introduction of milch goats. Better cooperation and understanding of Federal and State governments relating to Indian affairs is strongly recommended. The constant employment of the Indians, most of whom are industrious and willing to work, is urged. The committee is convinced that the Bureau of Indian Affairs is in no way disposed to pauperize our Indians, and certainly should be intrusted with sufficient funds for immediate relief of distress.

State boards of health are urged to enact laws to suppress vice and the mescal button (peyote habit), even for sacramental purposes. Peyote or pellote, (the Lophophora williamsii) and the mescal, (the Agava americana) both are strong narcotic drugs, not interdicted by the national prohibition amendment.

The report concludes with an urgent plea for cooperation with State and local antituberculosis organizations and educational and social societies, but very pertinently closes with the following significant statement: "No amount of health education will suffice to secure definite and lasting results until we improve their (the Indians') economic conditions and give them a chance to work and earn an honest living. When we extend a helping hand and evince a truly sympathetic interest in their welfare, and do as much uplifting work as we are disposed to do for our alien residents and among far away pagan races, we will have only in part discharged our obligations to the native race that has suffered so much and to whom we are so deeply indebted for possessing the immense natural resources of their native land."

INDIANS IDEAL TUBERCULOSIS PATIENTS.

Here I wish to say something in favor of the Indians afflicted with tuberculosis which perhaps is not generally recognized, and though it is only based upon the comparatively few observations which I have been able to make in the treatment of tuberculous Indians, I believe it to be significant. The Indian it seems to me is an ideal tuberculous patient by reason of his wonderful control of his nerves. The neurotic element, the restlessness and discontent which is found in so many tuberculous patients in the white race, is virtually absent in the Indian. He is a stoic and when properly reasoned with he will be an ideal patient and carry out the rest cure with an almost religious punctuality. Thus, if sanatoria for the Indians are placed as closely as possible to their former places of habitation, so that nostalgia does not enter as a complication, the percentage of cure in the early cases among Indians would, I am sure, be as high if not higher than among the tuberculous coming from the white race.

OFFICIAL REPORTS OF INDIAN MEDICAL SERVICE.

The remainder of this report of over one hundred pages furnishes numerous interesting tables and copies of official reports of the Indian Service, and lastly, as an appendix, gives an interesting historical sketch of the U. S. Indian Medical Service, which concludes with the very gratifying report of the present status as compared with thirty-five years ago. In 1888 the service had only four hospitals, in 1922 it had seventy-three, and during the World War and up to 1921, their number varied from eighty-one to eighty-five, although the medical personnel in the service in 1895 consisted of seventy-four physicians, eight nurses, seven hospital employees, and three field matrons, the personnel is now increased to two hundred physicians, one hundred nurses, one hundred hospital employees, and seventy-five matrons.

The report is signed by George M. Kober, M. D., LL.D., Chairman; George E. Bushnell, M. D., Joseph A. Murphy, M. D.; Albert B. Tonkin, M D.; William H. Baldwin, and Hoyt E. Dearholt, M. D., and is and will be a long time considered a classic document on the tuberculosis situation among the North American Indians. Its careful study should give food for thought, not only to the physician interested in the tuberculosis problem, but also to every American patriot, and above all to our American statesmen. Every one studying this report must realize that we have been found wanting in our duties toward the one hundred per cent. Americans and while much has been done for them during the past twenty-five years in improving their condition much more should be done.

Coexisting Intrauterine and Extrauterine Gestation

By JOHN M. KEYES, M.D.,
New York.

In an article on ectopic gestation from the viewpoint of clinical experience (1), published in 1910, I presented a detailed study of thirteen cases and mentioned among the complications the possibility of an intrauterine pregnancy occurring simultaneously with an extrauterine one. The following year I discussed in another article (2) three phases of ectopic gestation, considering the relative frequency of their occurrence, the mortality and the complications. In this second article I reported eight cases in detail and I pointed out that with certain known complications in mind and the proper surgical disposition of them, the mortality index could be kept low. Such cases as have come under my observation between the date of my last article and the appearance of the case I am about to report, have followed more or less orthodox courses.

On July 6, 1922, the following interesting case was referred to me by Dr. J. J. Kumpf, of this city:

CASE.—Mrs. C. R., aged twenty-nine years, was the mother of two children, the youngest twenty-two months of age. The patient had measles and diphtheria in childhood. Except for an occasional cold she had been in excellent health. She was well fed, plump, and robust in appearance. She first menstruated when fourteen years of age, was the twenty-eight day type and flowed, without pain, three or four days. The previous May the flow had come on and had continued one day on and one day off for one week. In June she flowed for one week and then had an active hemorrhage accompanied by cramplike pains, which she described as like those when she had a baby. She said she also had evening nausea, that being the type of nausea from which she had suffered during her earlier pregnancies. Vaginal examination revealed purplish mottling at the outlet, an enlarged uterus, and a mass to the right of it, tense, tender and fluid. Also some boggy thickness was found to be present in the posterior *cul-de-sac*.

The case was tentatively diagnosed as right tubal pregnancy and the patient sent to the hospital, where I operated on her within a few hours. Ether was administered by Dr. McNaughton. Assisted by the family physician, Dr. J. J. Kumpf, I first did a curettage, according to my custom. When the uterus was dilated there was an active hemorrhage and while the curette showed mostly decidual scrapings, a few shreds were suggestive of placental tissue. After a brisk curettage the hemorrhage stopped and as the patient had a very fat abdomen and as I was loath to put much pressure on it to manipulate the uterus, I decided to go ahead with the laparotomy, voicing to my associates the suspicion of the existence of an intrauterine gestation. Laparotomy revealed a uterus slightly tilted to the left just rising out of the pelvis and looking decidedly like one three months pregnant. I removed the right tube and ovary and also the thickened and kinked appendix. The left tube and ovary were normal. There was a fair amount of free blood and clots in the abdominal cavity. I closed the abdomen without drainage.

Postoperatively, a moderate bloody vaginal discharge and nausea continued for three days; otherwise the case was normal. On the fourth day the temperature rose to 102° and a fairly active hemorrhage with clots took place. The nurse reported finding fetal bones among the clots. On the following day, with the patient in dorsal decubitis position and without anesthesia, I removed a placental mass that was presenting at the cervix. I swabbed the uterine cavity with iodine and packed it with gauze. After this the nausea stopped and the patient had an uneventful recovery and was discharged two weeks from the date of admission.

Laboratory findings, by George L. Rohdenburg, for the Dr. Albert M. Pasca Laboratory, were as follows:

"Microscopic examination of specimen a shows a blood clot in which there are numerous chorionic villi, all in a good state of preservation. Specimen b shows an appendix in which the mucosa is intact and normal though the submucosa is thickened and richly infiltrated with round cells. The lymphoid elements of the organ show a marked hyperplasia. The muscular coats show no changes, the serous coat shows a recent inflammatory change characterized by a moderate proliferation with infiltration with round cells and a few polymorphonuclear leucocytes. Specimen c shows a connective tissue wall which is edematous and in which there are many round cells of irregular shape; in the latter there are many pigment deposits of brown, granular appearance. This pigment gives the Prussian blue reaction and is therefore iron. Internal to this connective tissue wall there is a blood clot which is undergoing organization, there being many connective tissue fibrils and newly formed bloodvessels extending from the connective tissue wall. Specimen d shows a Fallopian tube in which the wall is much thinned and in which there is extensive hemorrhage. None but the muscular and serous coats is identifiable. The mucosa is destroyed and replaced by a blood clot which is poorly organized and in which there are chorionic villi, some in a fair state of preservation, others appearing only as shadows. The ovary shows a slight fibrosis with a recent corpus luteum which is well organized. There are several simple follicle cysts of varying size scattered throughout the section.

"Diagnosis: Chronic productive appendicitis and periappendicitis with ectopic gestation."

"(Signed) G. L. ROHDENBURG."

My excuse for reporting a single case is that it is not the lot of every operator to come into contact with this condition and every individual experience of this kind is worthy of comment. Formad reports thirty-five ectopic pregnancies in 3,500 general autopsies. Edward Armin Schuman reports the incidence of tubal pregnancy to normal pregnancy for the city of Philadelphia, 1918, as .0033 per cent. The incidence of coexisting intrauterine and extrauterine pregnancy to tubal pregnancy is small. F. F. Simpson (3) reports 113 collected cases of coexisting intrauterine and extrauterine pregnancies with a maternal mortality of thirty-four. Parry, 1876, reported twenty-two cases among 499 ectopics, that is, 0.0441 per cent.

Formad's report shows ectopic pregnancy as a factor in one out of one hundred cases and the general experience of students of this condition is that during the childbearing period it is a comparatively common occurrence. It stands to reason, then, that the coexisting intrauterine and extrauterine pregnancies are somewhat more frequent than was formerly believed.

In my article on Three Phases of Ectopic Gestation (2), I pointed out that a chronic appendicitis with adhesions and a right tubal pregnancy were likely to coexist, the adhesions acting as a causative factor in tubal pregnancy by sacculating or kinking an otherwise normal tube. We had such a condition in this case. In the same article I drew attention to the fact that the proper disposition of complications tended to lessen mortality. The figures in Simpson's tabulated report show a maternal mortality of thirty-four in 113 cases. In this case of mine the suspicion aroused at operation tended to the easy and successful handling of the complication. My routine in ectopic pregnancies has been to do a preliminary curettage both for the purpose of arresting hemorrhage and also to render the uterine cavity sterile, but my experience with this case will prompt me to leave the uterus to deal with the decidua if that alone is what it has to deal with.

A number of these cases of double pregnancy are reported where the ectopic ones spontaneously took care of themselves or were removed by laparotomy while the uterine ones went on to term with a viable child. In going over the literature of coexisting intrauterine and extrauterine gestation I was struck with the fact that a great many cases were reported as interstitial and intrauterine pregnancies. That stimulated one's imagination to regard the mechanical factor as a causative agent in the distribution of these double pregnancies.

Further Experiences with Peptic Ulcers Accompanied by Deformities of the Viscus Visible by X Rays*

By MAX EINHORN, M.D.,
New York.

Last year I published a paper (1) reporting cases of peptic ulcers with deformities of the viscus evidenced by x rays, treated from April 1, 1921, to April 1, 1922. It was shown that these far advanced cases of peptic ulcer with niche formation along the lesser curvature and deformity of the cap are amenable to medical treatment. The same view is held by Hamburger (2) and Diamond (3), as cited in my article. H. Ohnell has likewise written extensively on this subject. At the time I published my paper I was not aware of his work, and I wish here to compliment his meritorious pioneer work in this line. Ohnell (4) reported six cases of gastric ulcers with niches which he cured by medical treatment. In order to be successful, he considers abstinence from food by mouth for a number of days, followed by a light diet (Leube) as essential. In a later paper (5), the same eminent clinician published his experiences with thirty-six cases of ulcers with niches. In ninety-two per cent. of these, perfect cures—that is, disappearance of the niches—were accomplished.

Notwithstanding the papers just mentioned and a few others expressing the same opinion, the question of the curability of peptic ulcers with niches is still doubted by a great many clinicians and by almost all surgeons. For this reason it does not appear inappropriate to publish so soon my further experiences with these cases. Before discussing the new material, however, I should like to review the condition of the patients described in my last year's paper. I regret that I cannot give an account of all of them, but shall state the progress of as many as I am aware of.

Of the six cases of ulcer with niche formations I know the condition of five. In case I (L. K., as described in my paper) the patient has gained about thirty pounds, eats everything, has no symptoms whatever, and attends to his business. In case II (Andrew R.), the patient who had the largest niche and was almost beyond help, feels perfectly well, and up to January 5, 1923, had gained over thirty pounds in weight and eats everything. In case III (Harry A.) is also in good condition and has gained in weight. The patient in case IV (Solomon D.) was well up to November, 1922, when he began to be troubled with upper abdominal pains, principally in the right hypochondrium. He was sent to the hospital for investigation. All the examinations, including x ray pictures, showed that there was no ulcer present—especially was there no reappearance of any defect or bulging out of the mucosa at the place where the niche had existed. It was found, however, that he had some gallbladder lesion to which his recent complaint was due. In case VI (John E. McC.) the patient improved considerably and gained in weight, but was advised by me to be operated upon on account of duodenal adhesions and gallbladder trouble. This was done and the patient is now perfectly well.

---

*Read before the New Mexico State Medical Society on June 20, 1923, Albuquerque, N. M.

Of the cases with duodenal ulcers described, four patients are in good condition, while I have not been able to follow the others.

In the present paper I wish to describe briefly the new cases of ulcers with deformities of the stomach or duodenum which I have observed in the year from April, 1922, to April, 1923. Five of these cases were affected with gastric ulcers and eight had ulcers of the duodenum. Some of these had partial obstruction of the pylorus also (Schneck and Henry M.). Two of the cases with niche formations I shall briefly describe while the others will be grouped in table form.

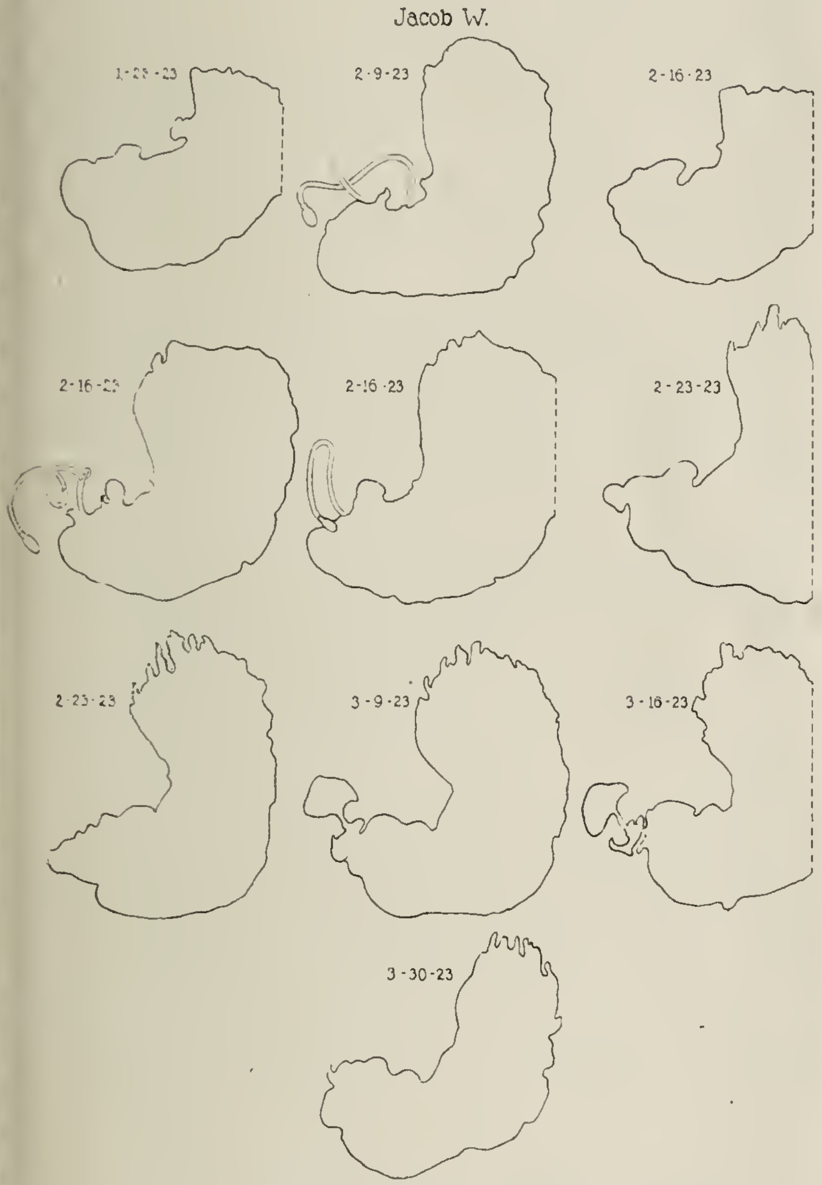

Fig. 1.—Case I. Jacob W. a, before treatment, January 23, 1923. Erect: niche of considerable size visible on lesser curvature. b, two weeks after treatment, February 9, 1923. Prone: niche has diminished to about one third its original size. c, three weeks after beginning of treatment, February 16, 1923. Erect: niche has diminished to about one sixth its original size. d, February 16, 1923. Same: oblique, niche more distinct. e, February 16, 1923. Same: prone. f. One week after removal of tube or four weeks after beginning treatment, February 23, 1923. Oblique: niche has diminished to about one tenth its original size. g, February 23, 1923. Same: prone, niche hardly noticeable. h, March 9, 1923. Six weeks after beginning treatment. Oblique: hardly a trace of niche visible. i, March 16, 1923. Oblique: hardly anything noticeable. j, March 30, 1923. Nine weeks after beginning treatment. Oblique: perfectly normal; not a trace of niche noticeable.

Case I.—Jacob W., a widower, forty-four years of age, a laborer, born in Hungary. He was admitted to the hospital in January, 1923, with a diagnosis of penetrating ulcer of the stomach. His family history was negative. Five years previously he had a chancre and was treated for five weeks. Four years ago he had an attack of gastric trouble

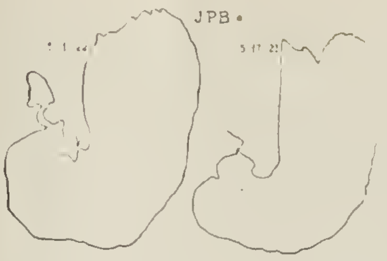

Fig. 2.

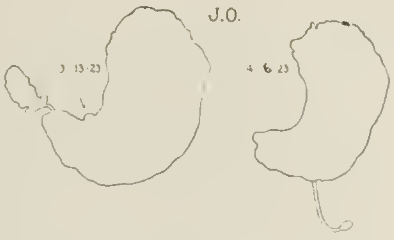

Fig. 3.

Fig. 2.—J. P. B. (Case I, table). a, May 1, 1922, before treatment. Niche on lesser curvature visible. b, May 17, 1922, after treatment. Niche has disappeared.

Fig. 3.—J. H. O. (Case II, table). a, March 13, 1923, before treatment. Oblique: Niche of considerable size on lesser curvature. b, April 6, 1923, after treatment. Oblique: Niche has entirely disappeared.

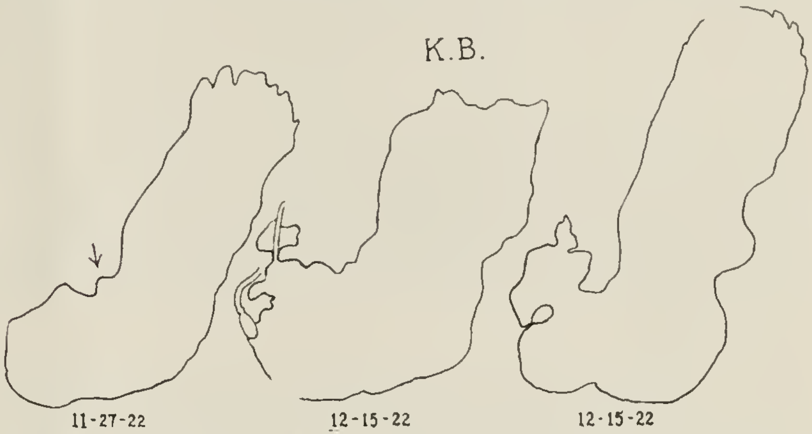

Fig. 4.—Karl B. (Case II, text). a, November 27, 1922, before treatment. Medium size niche visible on lesser curvature. b, December 15, 1922, after treatment. Tubes visible in duodenum. Niche has almost disappeared. c, December 15, 1922. Same, erect; not a trace of niche noticeable.

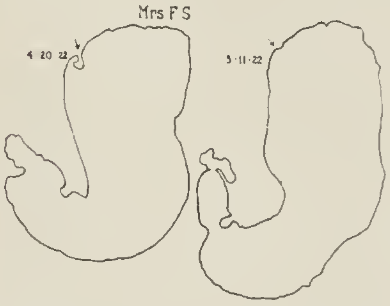

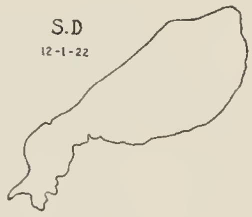

Fig. 5. Fig. 6.

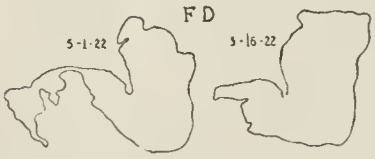
Fig. 5.—Mrs. F. S. (Case III, table), a, April 20, 1923, before treatment. Defect in cardiac portion of stomach visible. b, May 11, 1923, after treatment. Defect has disappeared.

Fig. 6.—Solomon D. December 1, 1922. Re-examination of patient—reported in last year's paper and mentioned in text of present article—shows no return of the niche.



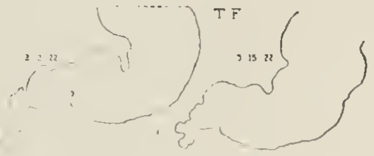


Fig. 7. Fig. 8.

Fig. 7.—Frank D. (Case IV, table). a, May 1, 1922, before treatment. Considerable defect in pyloric portion. b, May 16, 1922, after treatment. Defect has almost disappeared.

Fig. 8.—Timothy F. (Case V, table). a, February 2, 1922, before treatment. Deformed, lengthened and rigid pylorus. b, May 15, 1922, after treatment. The deformity is less marked.

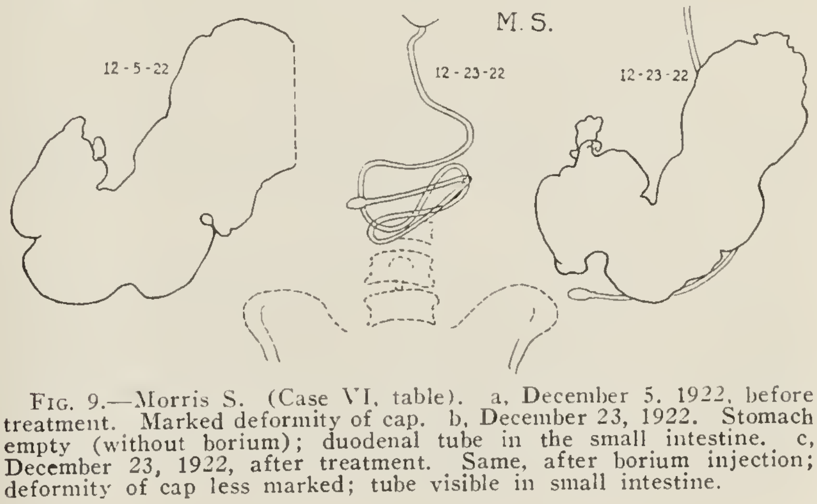

Fig. 9.—Morris S. (Case VI, table). a, December 5, 1922, before treatment. Marked deformity of cap. b, December 23, 1922. Stomach empty (without borium); duodenal tube in the small intestine. c, December 23, 1922, after treatment. Same, after borium injection; deformity of cap less marked; tube visible in small intestine.

similar to that for which he was admitted, which lasted for seven weeks.

The onset of the last attack occurred in October, with sudden severe pain in the epigastrium. This pain persisted on and off to the time he was admitted to the hospital. The pain was located in the epigastrium, radiating to the chest, and came on one or two hours after meals. The ingestion of food slightly relieved the pain, which was worse at night. During the first three weeks of the attack the patient suffered from persistent vomiting after each meal. This subsided after dietetic treatment in a hospital.

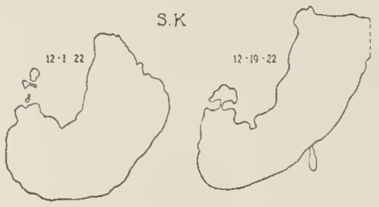

Fig. 10.

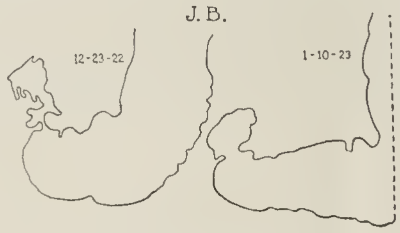

Fig. 11.

Fig. 10.—Siegmund K. (Case VII, table). a, December 1, 1922, before treatment. Marked deformity of cap, with contraction of lumen. b, December 19, 1922, after treatment. Cap less deformed, almost normal; capsule end of tube visible in beginning of jejunum.

Fig. 11.—Jacob B. (Case VIII, table). a, December 23, 1922, before treatment. Persistent defect in the first portion of the duodenum. b, January 10, 1923, after treatment. Defect has disappeared; cap almost normal.

The patient had suffered from diarrhea for the week previous to admission, having five to six movements daily, and had lost forty pounds in weight in two months.

The physical examination showed the skin to be dry and scaly; the pupils unequal; the teeth infected —pyorrhea; the lungs dull all over; the heart slightly dilated to the right; and tenderness in the epigastrium. Temperature 102° F. on admission, but subsided in three days and was normal ever since. The Wassermann test was negative, as was also the string test. The gastric contents showed: Hydrochloric acid+50; acidity=60. Blood examination negative. The x ray pictures showed a big niche in the lesser curvature.

The patient was put on duodenal feeding for twenty-one days, at the end of which time he had no pain and had gained nineteen pounds in weight. He was discharged February 24, 1923.

During the duodenal feeding period, at the end of two weeks, the first control x ray picture of the stomach was taken. At the end of three weeks the tube was removed and another x ray picture of the stomach was taken, after which the patient was allowed a more liberal diet. An x ray picture was then taken every week, the gradual diminution of the niche being distinctly seen. On March 16, 1923, the patient reported that he had gained twenty-nine pounds since the treatment.

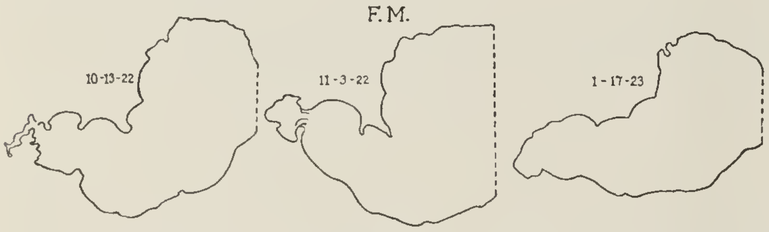

Fig. 12.—Fred M. (Case IX, table). a, October 13, 1922, before treatment. Marked irregularities in the prepyloric region, and deformity of cap. b, November 3, 1922, after treatment. The irregularities have disappeared and the deformity of cap has become less marked. c, January 17, 1923. The pyloric portion has assumed a more normal appearance.

Case II.—Karl B., fifty years old, was admitted to the hospital December 23, 1923, with a history of epigastric pain and vomiting for five years.

The patient began to complain five years ago of pain in the umbilical region, coming on three to four hours after eating, and was accompanied occasionally by vomiting. He had had ten severe attacks of this pain and vomiting within the past five years. Three weeks before admission the pain shifted to the epigastrium, and he suffered from severe vomiting three to four hours after meals. He had always been constipated, and had lost fifteen pounds in the last five years. There was no blood in the stools, and no blood in the vomitus. The physical examination showed the stomach dilated, extending to the symphysis (splashing sound). The gastric contents showed: Hydrochloric acid+acidity=50. There was no blood noted. The string test showed no blood stain; but there was bile present on it from twenty-four inches to the end. The x ray picture showed a niche on the lesser curvature, and six hour gastric retention.

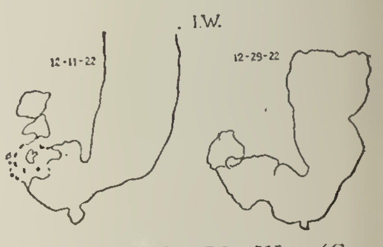

Fig. 13.—Miss Ida W. (Case X, table). a, December 11, 1922, before treatment. Sacculation in second portion of the duodenum, and defect in prepyloric portion. b, December 29, 1922, after treatment. Defect and sacculation have entirely disappeared.

This case is of interest in showing that the niche entirely disappeared in the short period of two weeks, under treatment by duodenal alimentation. In a letter from the patient under date of March 20, 1923, he states that he is feeling perfectly well, is eating a liberal diet, and is attending to his work as a chauffeur.

The rest of the cases are presented in the table on page 615.

Inasmuch as the reproduction of the x ray photographs is not always satisfactory when published, I prefer to give sketches made by an artist from the photographs taken in all these cases. They were all taken at the Lenox Hill Hospital and I, herewith, express my thanks to Dr. W. H. Stewart, the head of the department for röntgenology. The result of treatment, which was always duodenal alimentation, was very gratifying. In one of the patients (Henry M.) the pylorus was partially stenosed and the tube did not pass the outlet during a period of five days. I was inclined to have the patient undergo an operation (gastroenterostomy) but on account of his age (sixty-seven years) and his condition (he was suf-

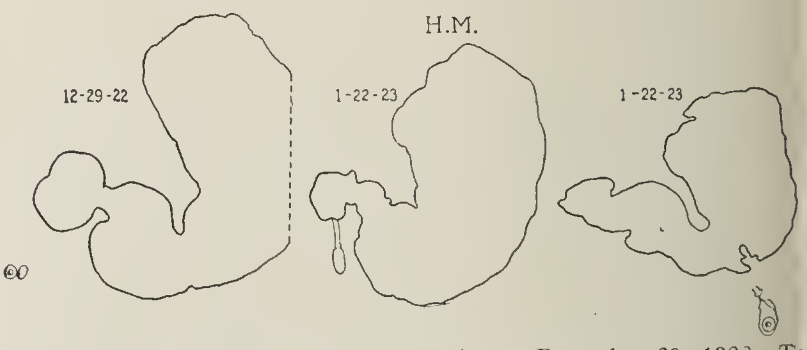

Fig. 14.—Henry M. (Case XI, table). a, December 29, 1922. To the right of the stomach two beads are visible, indicating that the digestive test capsule or beads have passed through the narrowed pylorus. b, January 22, 1923. The capsule end of the duodenal tube is visible in the duodenum. c, January 22, 1923. The bead attachment of the duodenal tube is seen in the beginning portion of the jejunum.

TABLE OF THE REMAINING CASES OF PEPTIC ULCER WITH DEFORMITIES OF THE VISCUS VISIBLE BY X RAYS TREATED FROM APRIL 1, 1922 TO APRIL 1, 1923.

No.	*Name*	*Symptoms*	*Physical Signs*	*String Test*	*Gastric Contents*	*X-Ray*	*Results*
1.	J. P. B...	Pains immediately after meals, duration 20 years. Occasionally vomits but no blood. Had an attack of hämatemesis 21 years ago. Has lost 20 pounds past 4 months.	Tenderness on pressure, stomach considerably dilated.	Positive; blood stain, 53-55 c. m.	HCl=+; Ac.=85.	Penetrating ulcer of lesser curvature, 6 hour gastric residue.	Niche disappeared, patient feels very well.
2.	J. H. O...	Past 2 years, nausea and vomiting; epigastric pains late after meals; food relieves pain.	Pains on pressure in left epigastrium, radiating to the back.	Positive; blood stain, 61-62 c. m.	HCl=+; Ac.=50; blood=+;	Penetrating ulcer of lesser curvature.	Niche has entirely disappeared; patient feels well.
3.	F. S......	Pain and burning in epigastrium for 15 years.	Tenderness on pressure right beneath the ensiform process.	Positive; blood stain, 35-50 c. m.	HCl=+; Ac.=90.	Irregular defect on the lesser curvature, high up at the cardia; slight gastric residue after 6 hours.	Defect disappeared; patient feels better.
4.	F. D.......	Lues 20 years ago; past 7 years pains after meals; melaena and hämatemesis; Wassermann++++	Tenderness on pressure under right costal margin.	Positive; blood stain, 43-56.	HCl=+; Ac.=85.	Defect on the greater curvature of the stomach in the prepyloric area; the cap is deformed; slight 6-hour gastric retention.	Defect has decreased; patient eats and feels well.
5.	T. F......	Discomfort in epigastrium for 6 years, no relation to food; hämatemesis and melaena once. Wassermann neg.	Pains on pressure beneath the ensiform cartilage.	Positive; blood stain, 55-57 c. m.	HCl=+; Ac.=112.	Duodenal ulcer with deformity of pylorus.	The deformity is less marked; patient feels well.
6.	M. P......	Past 12 years has had pain on and off in right hypochondriac region 2-3 hours after meals pain was relieved by eating; Wassermann=neg.	Liver enlarged. Pains on pressure in right hypochondrium stomach dilated and extending a hand's width below the navel.	Positive; blood stain, 50 c. m.	HCl=+; Ac.=40. Blood=neg. (feces neg. for blood.)	Deformity of cap in all films; slight 6-hour gastric retention.	Deformity lessened; patient feels well.
7.	S. K......	Vomiting on and off past 2 years; headaches one year; pain in right hypochondrium 3 weeks. Wassermann neg.	Tenderness on pressure in right hypochondrium.	Positive; double blood stain, as 56½ c. m.	HCl=0; Ac.=10. Lactic Acid =0. Blood =neg.	Cap contracted; considerable 6-hour gastric retention.	Deformity of cap less marked; patient feels better.
8.	J. B......	Duration 9 years with periods on and off lasting several weeks of epigastric distress one and one-half hours after meals; relieved by bicarbonate of soda. During the last 5 years there was also vomiting during the attacks.	Pain on pressure in the middle of the epigastrium.		HCl=82; Ac.=98; Blood=neg.	Persistent defect in the first portion of the duodenum.	Deformity and defect of cap have disappeared; patient feels better; has gained 30 pounds in weight; eats a liberal diet.
9.	F. W. M..	Duration 8 years; heartburn 3-4 hours after meals coming on in periods lasting several weeks, with few intermissions.	Tenderness in the entire epigastrium; stomach dilated extending 3 fingers' width below the navel.	Positive; blood stain, 42-52 c. m.	HCl=+; Ac.=70; Blood=neg.	Marked irregularities in the prepyloric region, suggesting ulceration with spasm.	Deformity of cap less marked; patient eats and feels well.
10.	Miss I. W.	Duration 13 months; epigastric distress, belching of gas, nausea right after eating.	Pain on pressure under right costal margin.	Positive; blood stain, 41-43 c. m.	HCl=+; Ac.=72; Blood=—	Peculiar sacculation in ascending portion of the duodenum just beyond its junction with the bulbus. Such finding usually indicate a diverticulum; slight 6 hour gastric retention and considerable retention in the diverticulum. (Dr. W. H. Stewart.)	Diverticulum has disappeared; patient feels well.
11.	H. M.....	Duration 10 years, epigastric distress on and off during this period. Diabetes mellitus for a number of years.	Tenderness on pressure in right hypochondrium, stomach dilated extending to the symphysis.	Positive; blood stain, 48-52.	HCl=+; Trace. Digestive test capsule appears after 50 hours; remaining some thymus (no nuclei).	Distinct pressure defect on the duodenum, suggesting some involveder.	Cap fills out better.

fering from diabetes mellitus), and also because he was strongly opposed to operation, I decided to make further efforts at medical treatment.

I attached a bead with a string to the capsule of the duodenal tube and had the patient swallow this contrivance. The bead being much smaller than the capsule, passed through the narrowed pylorus in twenty-four hours, and in another twenty-four hours pulled the capsule into the duodenum, and made the duodenal alimentation feasible.

While at first I thought that the disappearance of the niche was a mere possibility, I am now of the opinion that this is rather the rule, provided efficient treatment is instituted. It is, therefore, evident that these old peptic ulcers with deformities do not as such form an indication for surgery, for they can be healed. It is understood, of course, that there may at times be urgent reasons for intervention and that surgery may have to be resorted to, but in my opinion most cases can be healed by proper medical treatment.

Comparative Blood Studies in Smallpox and Chickenpox*.

By W. H. HOFFMANN, M.D.,
Havana, Cuba.

For several years in many parts of America epidemics of smallpox have been observed, which by their mild character were so essentially different from all former varieties, that there have been serious doubts about the question, if the disease really is identical with smallpox, or if perhaps a new disease is presenting itself similar to the one known as alastrim in Jamaica. I think, however, the opinion has been confirmed among sanitarians that the epidemics were undoubtedly true smallpox, though unusually mild in character. I may mention that in Cuba I have seen a certain number of cases generally considered as alastrim, which also must be attributed to true smallpox.

Also in Cuba the epidemic presented itself in such a mild form, that there were almost no fatal cases with the exception of a few in persons seriously debilitated by other diseases. At present, it seems that the epidemic has come to an end here, owing to the serious campaign undertaken against it from the beginning. The studies which I made were suggested by Dr. Guiteras in the desire to devise simple and rapid diagnostic methods in his campaign.

In the Las Animas Hospital I had occasion to see the cases which occurred in Havana or which were transferred here from the province during the last three years, and was able to study them with different laboratory methods. The results of my experiences, especially the inoculations made in the cornea of the rabbit, have also given me the conviction, that the disease was true smallpox[1]. At the same time there occurred many cases of varicella, which have been studied under the same conditions. It was always possible to differentiate the two diseases with absolute certainty.

During my studies I have made comparative investigations in the blood composition in the sixty cases of smallpox and forty cases of chickenpox here reported. In all the cases I made regular daily leucocyte counts and differential counts for forty days in smallpox and twenty days in chickenpox. The blood is by no means normal after those periods, but the observations could not be continued because the patients were discharged from the hospital.

In my opinion the results are of practical value, as they give a simple and reliable method, which may be used for clinical purposes and especially for the sanitarian to make an early and rapid diagnosis in doubtful or suspicious cases.

In many cases I made studies of the red cells and the hemoglobin content of the blood. Although I generally found slight degenerative changes, especially in smallpox, I should not attribute a great practical diagnostic importance to those findings, because blood degenerations are so frequent from other causes, especially in the tropics, that is scarcely possible to use them in the diagnosis of smallpox.

The study of the blood changes is so easy, that it should be omitted in no case in such an important and contagious disease as smallpox, the control of which depends so completely on early and efficacious sanitary measures. The results of the leucocyte counts, derived from my observations, are the following:

SMALLPOX.

The number of leucocytes is generally low in the first three days of the disease, about 4,000-6,000, with an average of 5,000. From the fourth day there will begin a marked increase of leucocytes, which reaches its highest values on the ninth day, with an average of 17,000, and which continues to the fourteenth day with a pronounced remission about the tenth to twelfth day. During this period it is not rare to find 24,000 to 30,000 leucocytes, and once I found 40,000 on the ninth day. Also during the third week there is still a pronounced leucocytosis of 10,000 to 12,000 as an average, and sometimes as much as 24,000. With the fourth week the leucocyte counts approached more to the normal, but as a rule there is still a slight increase during the whole period of observation during the fourth to sixth week, being 9,000 to 12,000 as an average; even numbers of 14,000 to 16,000 are not rare without other especial reason. It seems to me that the curve of leucocytes during the whole disease shows an oscillatory movement, which may be the expression of the oscillating fight between the virus and the antibodies produced by the organism. So I am also inclined to consider the leucopenia in the beginning of the disease as the expression of the insufficient resistance of the body against the virus of smallpox. I have the impression, that the leucocyte reaction is specifically directed against the smallpox virus and independent of the secondary suppurative germs, because I often saw a high leucocytosis previous to suppuration or even in many slight cases, which passed almost without any marked suppuration.

Besides the increase of numbers there are regularly considerable changes in the different classes of leucocytes, revealed by the differential count.

During the whole time of observation the polynuclear cells remain below the normal of 64 to 66 per cent. In the first six days the numbers are 30 to 20 per cent. and sometimes go down to an average of 12 per cent.; in the second and third week they rise slowly to 45 per cent. and keep between 30 to 40 per cent. in the fourth to the sixth week. Thus the decrease of the polynuclears is pronounced and characteristic during the whole disease.

The juvenile forms, normally not more than 1 to 3 per cent., in the first week are increased to 15 to 35 per cent. on an average, being highest in the first days. They remain increased to 4 to 10 per cent. during the whole observation. The transitionals are also increased during the first week; later their number is normal, about 1 to 3 per cent.

The eosinophiles are much increased in number and have an especial importance for diagnostic purposes. During the first three weeks they keep at 3 to 10 per cent.; during the fourth to sixth week the increase is still more marked, being 15 to 20 per cent. on an average, and occasionally as much as 30 per cent. As in many other acute infections in smallpox the presence of the eosinophiles may be considered as the expression of a powerful and favorable reaction of the body against the infection.

---

*Medical Research Laboratory, Health Department, Republic of Cuba.

[1] W. H. Hoffmann: The diagnosis of variola by inoculation of the cornea of the rabbit (*Medical Record,* November 26, 1921).

Corresponding to the marked decrease of polynuclears generally I found a pronounced increase of lymphocytes. With the exception of the first week almost all the counts have been above the normal of 24 per cent., as also the whole curve of average counts. The averages rise in the first week up to 45 per cent. and in the third up to 65 per cent. Also in the fourth to sixth week the curve is maintained between 40 to 50 per cent. During the whole period of observation of six weeks values of 60 to 75 per cent. are not rare. The lymphocytosis is also characteristic for smallpox.

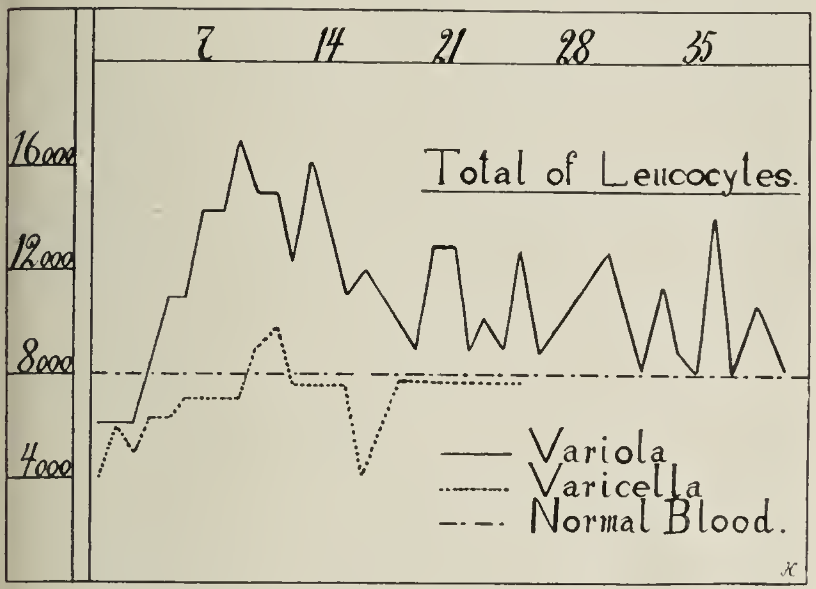

Fig. 1.—Total leucocytes in smallpox and chickenpox.

The large mononuclears are increased during the whole period from 4 to 8 per cent., the highest values being found in the first two weeks.

An especial importance in smallpox must be attributed to the presence of certain pathological cells, the myelocytes, which almost never are missed in smallpox, at least in the first three weeks, when on an average there are found 1 to 3 per cent. not seldom 4 to 5 per cent. and sometimes as much as 12 per cent. They have an especial importance in diag-nosis as they are not found in normal blood.

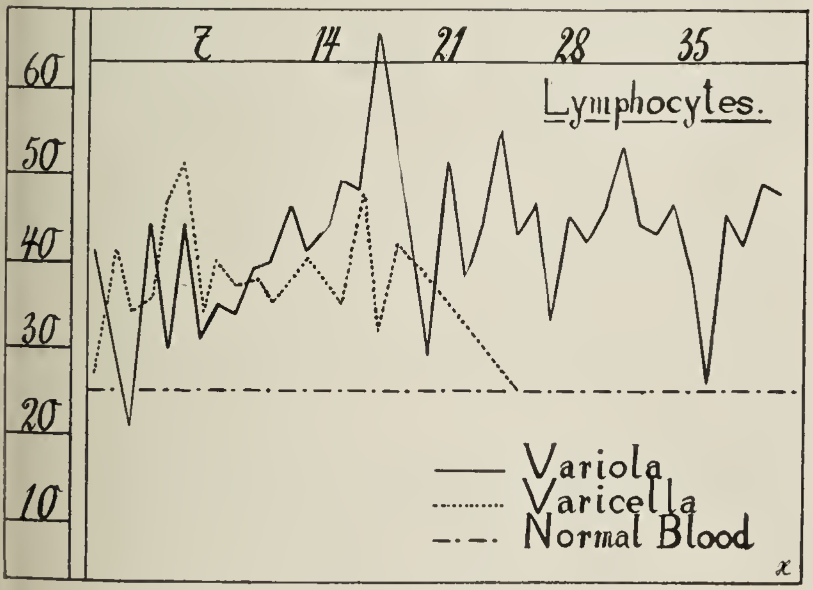

Fig. 2.—Lymphocytes in smallpox and chickenpox.

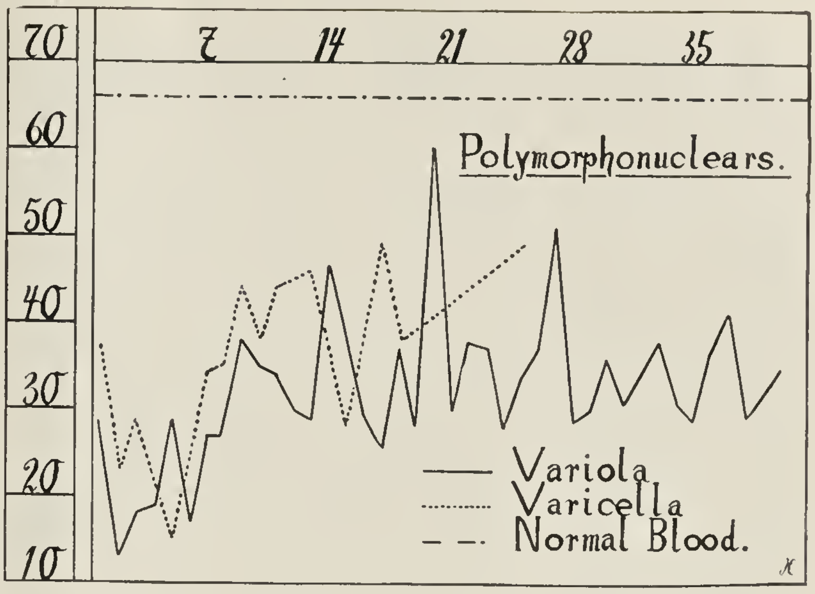

Fig. 3.—Polymorphonuclears in smallpox and chickenpox.

The study of the nuclei of the polynuclear cells after the method of Arneth has likewise revealed characteristic changes. In the first week the juvenile forms with one to two nuclei are markedly increased; later their number becomes normal. The cells with three nuclei are more or less normal in number. The forms with four to five nuclei, being low in number during the first week, are increased in the second to sixth week. Corresponding to those changes the Arneth index is high in the first week, rising to 90 instead of a normal number of 62. Later it is going down even to subnormal values and approaches the normal with the sixth week.

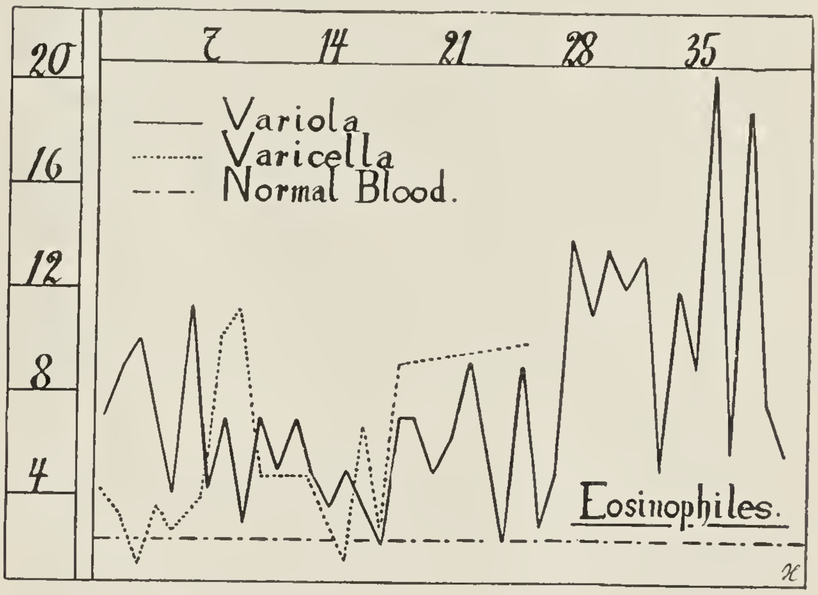

Fig. 4.—Eosinophiles in blood in smallpox and chickenpox.

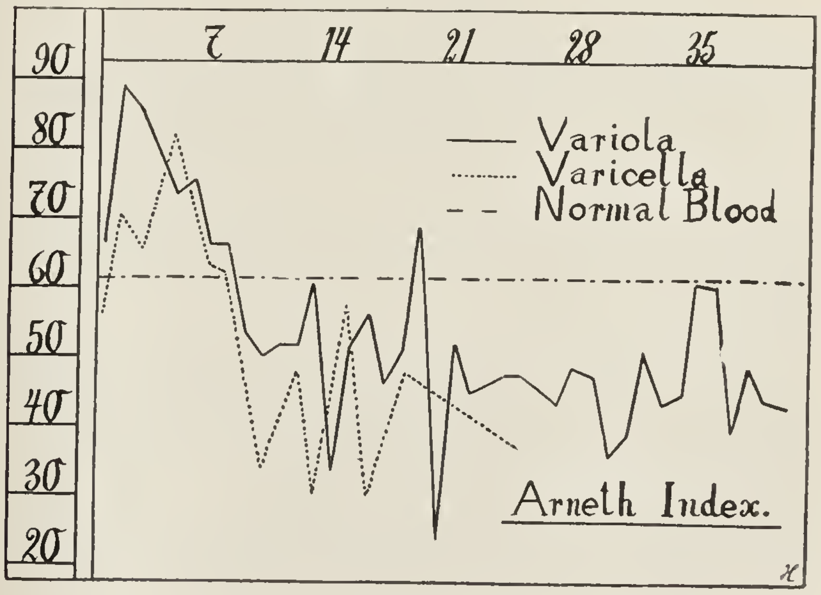

Fig. 5.—Arneth index in smallpox and chickenpox.

CHICKENPOX.

In chickenpox the total number of leucocytes is little affected by the infection. Generally in the first week the numbers are subnormal, between 3,000 to 7,000. About the ninth and tenth days the average number may be a little over the normal, because there are occasionally some cases with 10,000 to 12,000 leucocytes. After that time the total number goes down again to the normal and occasionally even to leucopenic values.

Whereas the absolute count thus scarcely shows any characteristic changes, the differential count reveals typical and pronounced alterations of the blood. The polynuclear leucocytes are diminished during the whole disease, the first week to an average of 30 to 15 per cent. and in the second to 45 to 30 per cent.; after that time the number is rising slowly to the normal.

The juvenile forms are especially increased during the first week up to 15 to 25 per cent. In the second and third week they go slowly down to 15 to 5 per cent. In a similar way the transitionals are increased in the first five days to 4 to 7 per cent. and later go down to 1 to 2 per cent.

The eosinophiles are not essentially increased during the first week. In the second to third week they are increased, showing values of 4 to 10 per cent. on an average. I could make very few observations after that time, but I think that the high number of eosinophiles continues for some time, perhaps being important for the cure of the disease and for the immunization of the body. On the twenty-fifth day I found still 10 per cent. eosinophiles.

The leucocytes during the whole period of observation are markedly increased up to 30 to 50 per cent.; in the first week the numbers may be as high as 75 per cent.

The great mononuclears are generally increased to 6 to 8 per cent.; sometimes the values are much higher, even more than 20 per cent.

Regularly I found myelocytes. In the first week they show an average of 1 to 2 per cent. and sometimes 4 per cent. In the second and third week they are less frequent and begin to disappear.

Consequently in varicella the total number of leucocytes generally is normal or even subnormal. There is marked lymphocytosis and corresponding to it a decrease of polynuclear cells. Eosinophilia is marked. Generally myelocytes are present.

CLINICAL APPLICATION OF THE RESULTS.

From my observations I conclude that the study of the blood can be used with especial profit for the diagnosis of the two diseases here considered.

In smallpox it is especially the marked leucocytosis, which after the third day has its importance for the diagnosis and must call the attention in suspicious cases and if found in repeated observations may give security to an otherwise doubtful diagnosis.

The diagnosis is still more supported by the differential count, which will reveal the characteristic changes in the numerical relations between polymorphonuclears and lymphocytes, the pronounced or even high eosinophilia, the presence of myelocytes, the changes of the Arneth Index.

In varicella there is no such increase of leucocytes, but here also exist pronounced changes in the differential count, which may be of practical diagnostic value and which are similar to those found in smallpox, with the inversion of the numerical relations between lymphocytes and polynuclears, marked eosinophilia, presence of myelocytes, and high index of Arneth at the beginning.

An especial importance under those circumstances must be attributed to the differential diagnosis of variola and varicella. We have seen, that the principal difference in the blood is given by the total number of leucocytes, which in variola is markedly increased after the first three to four days, whereas in varicella slight increases are met with only exceptionally about the eighth to ninth day. The differential count shows only significant gradual differences in the two diseases, which have no practical importance for the differential diagnosis. During the first three days the results of the blood study may be similar in the two diseases.

The hematological changes are so typical, that if they are missing in a suspicious case, this may be used with very much probability against the diagnosis of variola and varicella.

The results published here are averages abstracted from three hundred observations, all of which were made by me personally. Of course, in single cases the alterations may be found more or less pronounced, but principally all the countings without exception show the same wellmarked hematological character of the blood changes, which makes them such a valuable help for diagnostical purposes.

RESULTS.

In sixty cases of variola and forty cases of varicella comparative blood studies were undertaken with the intention to form an opinion about the value of such methods for clinical and sanitary purposes of diagnosis.

The differential count in both diseases reveals pronounced but identical changes, characterized by high lymphocytosis with a corresponding reduction of the number of polynuclears, high increase of eosinophiles, presence of myelocytes, changes in the Arneth index. Those changes show a distinction from other diseases with similar clinical symptoms.

For the differential diagnosis of the two diseases it is decisive, that in variola the number of the leucocytes is regularly highly increased for weeks, whereas in varicella there are normal numbers or only a slight increase from the eighth to the tenth day.

If in a clinically suspicious affection the typical blood changes are missing, the diagnosis of variola or varicella can be excluded with a fair degree of safety.

The changes are marked in variola for forty days and in varicella for twenty days at least, probably longer.

The degenerative changes in the red cells and the hemoglobin, though present, are slight and of no great specific importance especially in the tropics.

CONCLUSIONS.

The study of the changes of the leucocyte formula presents a practical and reliable clinical method for the diagnosis of smallpox and chickenpox. Probably further studies in other epidemics on the same line may help explain the character of the present epidemic. The question of alastrim might also be studied with good results by similar methods.

The Effect of the Placenta on Menstruation

By ADOLPH JACOBY, M.D.,
New York,
Associate in Gynecology and Chief of Clinic, Dr. Bandler's Service, New York Post-Graduate Medical School and Hospital.

The menstrual function is directly dependent upon the ovaries; without ovaries there is no menstruation. This has been so firmly established that it may be looked upon as axiomatic. It is equally true that for their perfect development and function the ovaries are dependent upon the other glands of internal secretion. It follows, therefore, that any change in the menstrual function must necessarily predicate a change in the function of the ovary and its aides; so that an increased function of these glands will produce an increase in the menstrual flow, and a decreased function of these glands, a decrease in the menstrual flow.

Now the menstrual flow is readily observable, and from its premenstrual manifestations, its regularity, duration, quantity of blood lost and accompanying phenomena, it is possible to arrive at a definite idea as to the function of the ovary and its associated glands. This being so one may use the menstrual flow as a therapeutic index in instances in which abnormalities in the function of these glands exist.

The glands which support the ovary, both trophically and functionally, are particularly the posterior pituitary, the thyroid and the adrenal, especially the cortical portion. Those which depress the ovary and its allies are the thymus, the mammary, and the placenta. The efficacy of the thymus and mammary in this direction has been studied in a previous series of cases, and it is to determine to what extent the placenta exercised this function that the present series of cases is reported.

It has been demonstrated that the syncytial cells surrounding the impregnated ovum from the earliest moment are thrown off into the circulation, dissolved and absorbed. These cells stimulate the continued growth of the corpus luteum. During this time and later when the placenta fully formed has assumed this function, the menstrual function is as a rule in abeyance and remains so for the full duration of the pregnancy.

It has been further demonstrated experimentally that the presence of the maternal decidua inhibits ovulation as long as the corpus luteum has not been removed. From its similarity in behavior, both chemical and thermal, the effective secretion of the placenta is thought to be analogous to the lipoid substance obtained from the corpus luteum cells. It is furthermore stated that the placenta exerts a restraining influence on the posterior pituitary and it is this inhibitory action which in part explains the effect of the placenta during its active existence.

In order to determine what practical value these considerations may have, a series of twenty-five cases was selected in which the extract of placenta was administered in five grain doses regularly three times a day. In all of these cases the patient had a menorrhagia of greater or less intensity, as a prominent symptom. The duration of the menstrual periods varied from five days to two weeks. In the majority of cases there was an associated dysmenorrhea. The onset of menstrual life occurred between twelve and thirteen years of age in eighteen instances.

The pathological conditions present included tubal and parametrial inflammation in sixteen cases, fibroids in three cases, subinvolution in three cases, retroversion in two cases, and cystic ovary in one case.

The pathological conditions tending to produce congestion undoubtedly cause a hypersecretion of the ovaries, as it is not likely that the increased menstrual flow is due merely to an increased vascularity of the organs concerned.

The placental extract was continued for at least three months in order to be certain of producing any action if it were effective.

RESULTS IN TWENTY-FIVE CASES.

The results were rather interesting, and in some cases remarkably prompt and quite pronounced. In the twenty-five cases observed four showed no change in menstrual function, and the other twenty-one cases, or eighty-four per cent., all showed a diminution of the amount of blood lost. The duration of the menstrual flow was reduced; whereas originally the flow lasted from five days to two weeks, it now lasted from two to seven days. In some instances the duration of flow was unchanged, but the amount of blood lost was noticeably diminished. The discomfort and pain during menstruation was considerably diminished in many instances. The blood pressure during the taking of the placental extract usually fell on an average of ten mm. No ill effects were reported from prolonged taking of the extract, except in a few instances in which nausea and vomiting occurred.

One of the cases under consideration presented several features of unusual interest, and so well illustrates the effectiveness of the action of placental secretion that a fuller report is here rendered.

CASE REPORT.

Case I.—The patient, thirty-nine years of age, was a native of Italy, by occupation an embroiderer. Her family history was negative, as was also her previous history, except for an attack of pleurisy twenty years ago.

Menstruation began at the age of twelve years, was established regularly in a few months, occurred every twenty-eight days, was of eight days' duration, very profuse in amount, and accompanied by pains on the first day. There were no clots. Premenstrual manifestations consisted of a sensation of fullness in the breasts and the head two days before onset of menses. The patient suffered from extreme weakness after menstruation due to loss of blood. She had been married fifteen years, pregnant five times. The first pregnancy, which occurred fifteen years ago, terminated at the eighth month, with the instrumental delivery of a stillborn child. During the next eight years she had been pregnant four times, each terminating in a miscarriage, the last, seven years ago, at the fifth month of gestation. She had had no operations, bowels were constipated, urination negative. There was a slight leucorrheal discharge, no abdominal or pelvic pain. The patient was very nervous, high strung, easily excited, and had a violent temper.

General examination showed a woman five feet in height, weight ninety-nine pounds, thin and undernourished; skin fine and soft; mucous membranes anemic; glands not palpable; heart and lungs negative; pulse rate 84; abdomen negative.

A pelvic examination showed that the external genitals were negative; the urethra was negative. The pelvic floor showed a moderate laceration and relaxed pelvic outlet. The vagina was relaxed. The anterior wall showed a slight cystocele and the posterior wall a beginning rectocele. Cervix showed a bilateral laceration with scar extending into both lateral fornices of the vagina. The uterus was anteflexed, fundus freely movable, normal in size, outline and consistency; no tenderness. Adnexa were normal on both sides. Parametrium was negative. Cystoscopic examination revealed normal bladder wall, trigone and ureteric openings. Urine was negative. Blood Wassermann and complement fixation tests for gonorrhea were both negative. Blood pressure was 120-80 at the beginning of treatment, 105-70 three months later.

TREATMENT.

Treatment consisted of the administration of the extract of placenta five grains three times a day for two months. The first menstruation following the administration of placenta lasted two days, was slight in amount, with no pain and no clots. The second menstruation, twenty-eight days later, lasted two days, was slight in amount, no pain, no clots. The extract of placenta was discontinued. The third menstruation, twenty-eight days later, lasted two days, was also slight in amount, with no pain and no clots. During this time the patient said she felt better, was not so irritable and excited as heretofore. The patient failed to report after her next period, and I lost sight of her.

COMMENT.

The facts which point to the endocrine origin of the disturbance in this case may be enumerated as follows:

1. The early onset of menses indicating great activity of the glands controlling the menstrual cycle.
2. Profuse menstrual flow indicating hypersecretion of the ovary and the glands associated with it.
3. Repeated miscarriages indicating excessive stimulation of the uterine musculature due to hyperactivity of the posterior pituitary.
4. Marked underweight, thin and soft skin indicating excessive activity of the posterior pituitary and perhaps the thyroid.
5. Extreme nervousness, restlessness, and excitability, indicating hyperactivity of the thyroid and posterior pituitary.
6. Marked improvement produced by appropriate therapy.

In this case the response was rather more marked than the average.

While it is undoubtedly true that twenty-five cases are not a very large number from which to draw conclusions, yet the large preponderance of successful cases, and the long period over which they were observed, lend encouragement to the view that the secretion produced by the placenta is effective in controlling the hyperactivity of the ovary and the glands aiding it in its function, more especially since it is supported, not alone on theoretical and experimental grounds, but also by that ultimate criterion of all theory and therapy—results.

1141 Fox Street.

Threadworms in the Appendix

By LAMBERT ROGERS, M.R.C.S., Eng.,
London.
Late House Surgeon, The Middlesex Hospital.

Intractable cases of threadworms are occasionally met with. Osler records the case of a man of forty who had been subject to oxyuris vermicularis all his life and in whom all treatment had been ineffective.

It is conceivable that in cases of this type a nidus exists in some part of the alimentary tract not easily reached by ordinary anthelmintic treatment. This was observed in the following case:

Case.—Miss P. R., aged twenty-eight, had suffered from threadworms since childhood. The usual anthelmintic treatment, which had been carried out conscientiously on a number of occasions, was ineffective, the condition constantly recurring. My colleague, Dr. A. Brown, pointed out to his patient that her appendix might be the source of the infection and she clamored for something further to be done.

I was asked to see her and on January 29, 1923, removed a retrocecal and fibrosed appendix through the usual muscle splitting incision. On taking off the clamp from the base of the amputated appendix threadworms crawled out of the lumen in great numbers.

The patient left the hospital on the fourteenth day and has not passed a threadworm since the operation.

No doubt other cases of this nature occur, a focus of nematode infection existing either in the appendix or a saccule of the colon.

Corneal Injuries in Industrial Occupations*

By FRANK ALLPORT, M.D.,
Chicago.

Among the most frequent accidents to the eye encountered in industrial work are those cases where small foreign bodies are driven into the eye from emery wheels or other causes, and find lodgment either in the ocular cul de sac, or in the eyeball itself, and usually in the cornea. If the particle is in the cul de sac, it can either be found floating under the lower lid, or more usually, on the conjunctival surface of the upper lid, midway between the inner and outer canthi, from whence it can be easily removed by a cotton loaded toothpick, after the upper lid is everted. But if the particle is imbedded in the eyeball (and usually in the cornea) an entirely different condition confronts us. This kind of work should always be done under strict aseptic conditions, with clean hands and instruments, with local anesthesia, with concentrated illumination, with good light, and with strong magnifying glasses. I think I have seen more sad ocular outcomes from a neglect of these precautions, than from any other one cause, and yet, this kind of work is regarded as trivial by those who *should* know better.

Let us suppose that a foreign body has found lodgment in the cornea (and that a pigment spot in the iris has not been mistaken for a foreign body on the cornea—a mistake that is not infrequently made) two conditions should be ascertained, viz., the *location* of the particle, and the depth of its situation. If the invader is lodged outside the ordinary pupillary area, the situation is much less serious, but if it is lodged within the pupillary area, the case must be regarded with more apprehension. The reason for this is the extent and density of the scar that is so often the result of the operation of picking these particles from the tissues of the cornea.

The problem that confronts us is to remove the foreign body with as little corneal damage as possible, and without producing infection. Fortunately most forcibly driven particles are in themselves aseptic, rendered so by the friction of the blow, and the rapid passage through the air. Particles that fly through the air, however, from a smokestack, dirt from the streets, etc., are usually septic, and may be the initial cause of infection. They fly through the air, and perhaps lightly lodge in the cornea, or are rubbed in by the patient rubbing his eye after the accident, instead of leaving it alone, or washing it out, or lifting the lid, or going to an oculist at once for relief. Objects of this kind can usually be easily brushed from the cornea (after anesthesia) by cotton tightly twisted on a toothpick, and moistened in a mild antiseptic solution. Afterwards the eye should be irrigated, and argyrol solution and a bichloride ointment used, and this will usually end the case.

But when the foreign body is firmly lodged in the corneal tissues, an entirely different situation confronts us, for the object must then be picked out of its bed by an instrument such as a spud or cataract knife. The surgeon's hands, instruments, etc., should be strictly clean, the eye should be freely irrigated with boric or some such solution, the eye should be anesthetized, the light should be ample (either gas or electricity) and focussed upon the spot of operation by a strong convex lens held by an experienced assistant. The operator should magnify the illuminated spot by a strong convex lens held in his own hand through which he should look. He is thus working in an illuminated magnified area, and thereby to the best advantage. Some foreign bodies can be easily picked out with little or no corneal laceration, others require great experience, patience and ingenuity for their removal. Some are covered by a real corneal flap, others are so deeply imbedded that there is great danger of rupturing the cornea in the effort at removal, in fact, this unavoidable accident does sometimes occur, and the particle may drop into the anterior chamber, rendering an operation for its removal by a magnet or otherwise necessary. If it is steel, the magnet will withdraw it. If not, the opening of the cornea with a keratome may give it an impulse to present at the opening, from whence it can be picked out with forceps, or, it may be necessary to wash out the anterior chamber with an irrigator, in hopes of flooding the invader out, or sometimes it will be imperative to remove the foreign body through a keratome, opening by delicate toothless forceps. Jackson and others have devised magnifying glasses to be worn on the head, thus giving one the use of both hands.

In removing obstinately lodged foreign bodies, the greatest care should be exercised to do as little damage as possible, remembering that every scratch of the knife will leave a scar, and that eyesight will be impaired in direct proportion to the amount of scar tissue produced. This is especially true, of course, when the foreign body is lodged in or near the pupillary area. It is difficult to describe just how the foreign body shall be removed by the knife or spud. I think that experience is the best teacher. Three rules, however, should be observed: 1, get the instrument under the foreign body if possible, and lift it out; 2, injure the cornea as little as possible; 3, always work under ample and concentrated illumination. The eye should, of course, be thoroughly anesthetized, and foreign bodies and corneal abrasions can always be better seen if a fluorescin solution (two per cent.) is dropped in the eye, and then partially washed away by a bland irrigating solution. Personally, I like to stand behind the patient with his head resting on a headrest or my own breast. It is sometimes difficult to find the particle, it is so small, and the patient should look in all directions, and hold the eye as quiet as possible. Sometimes a particle can only be seen by getting a profile view of it, assisted by the staining properties of fluorescin, and one should be careful not to mistake a pigment spot in the iris for a foreign body in the cornea—a mistake that is not infrequently made —and (unfortunately) acted upon. After every particle of foreign material is removed (and the invader sometimes breaks up into a number of pieces) it is advisable to look the cornea over and see what has happened. Sometimes the foreign body is hot when it reaches the cornea, and is driven into its tissue, and a brown eschar is formed all around the site of injury. Authorities differ as to the advisability of removing this eschar. Some believe in leaving it alone, that it does no harm, that it is an actual protection to the underlying cornea, and that it will fall off in due course of time like a scab. Others believe that it acts like a foreign body and should be removed, which is easy to do. Personally I incline to the former belief, but I remove the eschar for the simple reason that inasmuch as the eschar is dark brown in color and looks like a foreign body, the friends of the patient invariably discover it and tell him that I have not removed the foreign body and do not understand my business.

---

*Read before the Chicago Medical Society, December 6, 1922.

I have tried leaving the brown eschar many times but have been compelled invariably to take it out the next day on account of the dissatisfaction of the patient and his friends. Unless the foreign body is removed easily, the cornea is more or less damaged and needs attention. In the first place, the particle itself has injured the cornea by nesting in its tissues. Then the spud or knife (even where great care is exercised) injures the corneal tissue to a greater or lesser degree. Besides this, if the particle has been lodged for some time, especially if it carried infection with it, a state of ulceration has already begun, and serious consequences may ensue, especially if proper and vigorous treatment is not begun immediately. Where there is no ulceration, and hardly any corneal abrasions, the case may be treated with irrigation—argyrol solution (twenty per cent.) and bichloride ointment, and watched for a day or two. But if there is ulceration, or the cornea is much injured, it is advisable to gently touch the pathological tissue with carbolic acid. For this purpose a fine end of a toothpick is used, and a little cotton is tightly twisted on the point. This is dipped into carbolic acid, the superfluity of which is wiped off by touching it to a piece of gauze. The acid is then applied gently to the abraded cornea, and if the directions here given have been followed, the acid will not run or invade the healthy corneal tissue. Sometimes, however, if the ulceration has already begun, and is active, it will be well to have the cotton loaded toothpick act not only as a cauterant, but also as a curette, scraping up the dead tissue, and cauterizing the diseased area as well. The eye should then be irrigated —argyrol twenty per cent. solution instilled, also atropine solution and some bichloride ointment put in the eye and a gauze and cotton pad put over the eye and held in place by adhesive strips.

I consider it very important in these cases of corneal injuries, that the eye be protected by a pad. This prevents irritation and infection from the air, and the invasion of the eye by additional and irritating foreign bodies. This is the time to protect the eye from serious trouble, and if a few hours of protection and quiet will produce a healthy eye, then by all means give the patient the benefit of the wiser course. Of course when a foreign body can be brushed off from the eye with some cotton, there is no necessity for ordering a detention from business, but when there is any danger in sight, by all means give the patient the benefit of the doubt. I have had ignorant and selfish employers write me abusive letters for not returning employees immediately to work, when I am only trying to protect them from paying heavy damages for lost eyesight, and at the same time conserve the vision of the unfortunate injured man. If all goes well, the man may be returned to work the next day, but if there is any corneal abrasion as shown by the fluorescin staining, the man should remain under treatment until the cornea is completely healed. Corneal ulcerations are dangerous things. Ulcers and scars may occur in other parts of the body and no harm is done, but once infection of the cornea gets under way, it may spread with incredible speed, and in a few days the eye may be ruined or enucleated, or, at the best, dense extensive scars occur that produce much loss of vision and even blindness. Let no one speak flippantly of apparently trivial corneal injuries. There is no such thing. They all possess potential possibilities that should create anxiety until the safety point is reached.

It may be necessary from time to time to use other cauteries than carbolic acid. For instance, I sometimes use equal parts of carbolic acid and tincture of iodine, and sometimes fuming nitric acid, although great care should be exercised in its use, and as little used as possible. I have, of course, used a good deal the actual electric cautery, but it is so easy to puncture the cornea while using it that I have not used it much of late. Dr. Prince of Springfield, Ill., has devised an instrument which he calls a pasteurizer. It is a cone shaped mass of steel with a handle attached. The cone is heated in a spirit lamp until it is white hot, and then it is held a short distance from the ulcerated cornea. This is supposed to kill the bacteria. I have tried this instrument a good many times and have been disappointed in its use. Maybe I have not used it just right. I, however, like the instrument much for applying the actual cautery to a corneal ulcer. I heat it in a spirit lamp and then touch the ulcerated areas with the apex of the cone. The apex is rounded and blunt, and there is not near the danger of perforating the cornea that there is when the delicate heated electric wire is applied to the cornea.

In the treatment of bad corneal ulcers and their sequelæ, I have been much disappointed in the use of subconjunctival injections of bichloride, salt, dionin, etc. They are all painful, especially the mercurial injections, and patients almost invariably attribute all the disasters that follow to the injections. After giving them all a fair trial, I have abandoned them, and I can say the same of the subcutaneous injections of milk. I do not use it any more, and believe that its beneficial influence has been much exaggerated. Remedies of this nature sometimes acquire an undeserved reputation by ardent experimenters because a patient or two have done well while they have been used. This is no proof at all, but nevertheless does not deter them from rushing into print with glowing accounts of the wonders that have been performed. Prolonged use and much experience with careful and conscientious observations, alone warrant a claim of definite results for any remedy.

What then do I do for these dreadful cases of deep sloughing corneal ulcers, followed frequently by hypopyon, or pus in the anterior chamber, iritis with adhesions, panophthalmitis, and enucleation? I search for outside causes such as syphilis, kidney lesions (for diabetes sometimes plays a conspicuous etiological rôle in the tragedy), diseased teeth, tonsils, sinuses, lacrymal diseases, etc. X ray pictures and modern transillumination are of great assistance in searching for these causes. If I find any focus of trouble I try to relieve it as far as is consistent with the patient's ocular condition. I have seen removal of the tonsils or diseased teeth, and draining of some of the head sinuses play a wonderful part in some apparently hopeless cases of ocular infection. I put the patient to bed and give him a cathartic and plenty of water to drink. I regulate his diet and see that he is not overfed. I give him about 120 grains of salicylate of soda in twenty-four hours, and direct that he shall have a mercurial inunction once a day—rubbing in with the palm of the hand, a piece of mercurial ointment about half as large as a peanut, for fifteen minutes by the clock—into some hairless portion of the body—and then washing off what is left with soap and water. The place in the body should be changed from day to day to avoid dermatitis. If he has trachoma or hypertrophic papillary conjunctivitis, I give his everted lids a thorough brushing with a toothbrush and boracic acid powder two or three times a week, and have helped many very stubborn cases by this procedure. Where trachoma and corneal ulceration occur in the same eye, copper crystal, strong solutions of silver nitrate, etc., should not be used; they increase ulceration.

To the inexperienced, exclusion of copper crystal, etc., and inclusion of tooth brushing the lids may seem like curious advice, as, at first thought, the tooth brushing process would seem to be more severe than the copper crystal treatment. This presumption, however, is erroneous. Tooth brushing or brossage is not irritating. Its beneficial effect on the ulceration is sometimes immediate. The smoothing of the palpebral conjunctiva and the hemorrhage from the brushing, have an antiphlogistic and soothing effect upon the ulcer, while the brushing of the lids with the copper crystal, even if thorough irrigation is used thereafter, seems to produce a lingering and potent irritation, extremely detrimental to the integrity of corneal tissue. The brossage should be followed, of course, by suitable treatment for the lids. The ocular secretions should be examined in the laboratory, and this will sometimes guide us to the best remedy to use. I may say, however, that most of these cases require rather strong solutions of argyrol, probably about a twenty-five per cent. solution. The tear ducts should be carefully examined for pathology, and if disease is found, it is best to open the lower canal, pass a large probe, and in a few days to irrigate the canal with an antiseptic solution such as argyrol. These irrigations should not be made for several days, however, for if liquid is passed through the passages before the cut surfaces have healed, the liquid is apt to pass into the neighboring tissues and produce an ugly swelling—and if argyrol is used, an indelible staining of the tissues. The nose should also be examined and if ethmoidal disease, a badly deflected septum, polypus, or other obstruction or disease is found, steps for relief should be promptly taken. If he has syphilis, I see that he has proper treatment. I cauterize the ulcer when necessary, but cauterization should not become a routine habit with the surgeon. The eye should be given a chance to get well, and sometimes too much cauterization blocks recovery.

In my hospital we use what is called the intensive treatment in such cases. This consists in using a drop of one per cent. atropine solution every five minutes for half an hour (six applications). Where atropine is used so freely, great care should be taken to prevent constitutional effects. The nurse should stand behind the patient and pull up the upper lid. She should then allow one drop to flow over the cornea, and then press the tear duct for a moment with the finger to prevent the atropine running down the tear passages into the nose and throat. In this way the danger of constitutional effects will be reduced to a minimum. Meanwhile, during the half hour period, heat is continually applied to the eye. I prefer an electric bulb with gauze around it, but if this is not possible, hot water may be applied with thick gauze cloths or with a hot water bag. The heat should be as strong as the patient can bear. At the end of the half hour of atropine and heat, dionin should be used, commencing with a five per cent. solution. A ten per cent. solution will soon be necessary, and then even the powder. A marked edematous condition of the conjunctiva should be produced, and dionin soon wears out its power on one individual, and increased strength from time to time becomes necessary. When even the powder no longer produces edema of the conjunctiva, it may be stopped, for it is no longer useful and is only an irritant. In ten or fifteen minutes after the dionin has been used, the treatment may end by putting in the eye some bichloride and atropine ointment. This completes the treatment, but it should be gone through with three times a day. If it is thought that the dionin is producing too much irritation, it can be used only once a day. If atropine produces unpleasant effects, its use will have to be diminished, or even stopped, at least temporarily. Argyrol solutions may be used during the treatments. Almost all cases of ulceration of the cornea will yield to this treatment.

I have often thought that good results were obtained in these bad cases by the use of pilocarpine or other sweats. They should be given daily for a few days and then at intervals. When pus forms in the anterior chamber, the treatment just outlined will frequently dissipate it. But, of course, in many cases the pus remains and increases in volume. In such cases I open the lower portion of the cornea at the floor of the anterior chamber with a rather broad keratome, and wash away the pus with warm normal salt solution and my anterior chamber irrigator. This will sometimes stop the progress of the disease, but unfortunately many of these cases are so virulent in their nature that pus reaccumulates, and the eye is lost from a general panophthalmitis and enucleation becomes necessary. This, then, is the end of many cases of neglected or poorly or even well treated minor corneal injuries. The lesson to be learned is—let such minor injuries be properly treated from the very start.

Retrobulbar Neuritis Associated with Diseases of Nasal Accessory Sinuses

With Report of Two Cases

By EMANUEL L. FALK, M.D.,
Brooklyn, N. Y.,
Clinical Assistant, Manhattan Eye, Ear, and Throat Hospital (Eye Department).

While much has been written on the subject of diseases of the eye caused by diseases of the nasal accessory sinuses, this report of two similar cases of retrobulbar neuritis is made to call attention again to the intimate relationship that exists between diseases of the optic nerve and diseases of adjoining structures, and emphasize the importance of early recognition of the causes in cases of amblyopia and its proper treatment before signs of optic atrophy occur.

The relation between affections of the nasal mucosa and superficial eye conditions is often clinically observed (such as diseases of the conjunctiva lacrimal and cornea). We now recognize also that there is a connection between deeper seated and more serious ocular disturbances and diseases of the nasal accessory sinuses. These conditions may be caused by absorption of toxins from a focus of suppuration within the sinuses, acting just like a focal infection in other parts of the body, such as iridocyclitis, which I observed recently was cured by operation on the nasal accessory sinuses, or by direct contact between a pathological process in the sinuses and some ocular structure.

I shall confine myself however to inflammation of the optic nerve in the form of retrobulbar neuritis, manifesting itself only by disturbance of vision and a central scotoma without visible changes in the nervehead on ophthalmoscopic examination. The visual defect varies greatly, from an enlargement of the blind spot, only to be detected by careful perimetric examination, to the loss of light perception.

Retrobulbar neuritis is located in the orbital division of the optic nerve; hence seldom do we find changes in the papilla upon ophthalmoscopic examination, but in the later stages, or, when the disease subsides, signs of atrophy frequently make their appearance.

This takes place when the destruction of the fibres of the optic nerve has taken place, within the region occupied by the focus of inflammation. In most cases the disturbances of vision are confined to the central portion of the visual field which are supplied by the papillomacular bundle.

The lesion of this bundle may be even so slight as not to interfere with acuity of vision at first, and, if we simply stop at determining this, we may not discover any disease of the optic nerve at all; but by testing out the visual field, with a small colored object, it may show a diminution in the centre, the ability to appreciate color. Especially is it important to test out the blind spot; which, according to Van der Hoeve, enlargement of the blind spot could be detected much earlier than the visual field defect and is an early sign of posterior sinus trouble. (This probably explains the reason for the rarity of optic nerve trouble as compared with posterior sinus trouble which is common.) In some cases, however, the lesion increases rapidly to the point of complete blindness; as the subjoined cases demonstrate.

PATHOLOGICAL ASPECT.

Fuchs gives the following explanation. "In the optical canal, the dural sheath of the optic nerve is transformed into the periosteum of the bony canal; hence the optic nerve in this situation is enveloped only by the delicate pial sheath, which in most places is applied to the periosteum and on the upper side is actually adherent to it. This anatomical relation facilitates direct transfer of inflammation from the cavities in the vicinity of the canal to the optic nerve itself.

This inflammation first affects the pial sheath of the nerve, and we should therefore expect that the peripheral bundles of nerves which are next to this sheath would be the first diseased. These bundles supply the periphery of the retina; but in these cases on the contrary it is the centre of the retina that becomes insensitive, hence a central scotoma; which proves with certainty that there is a lesion of the papillamacular bundle, which in the canalicular segment of the nerve occupies just the middle of the nerve trunk, i. e., it is the part farthest distant from the inflamed sheath. This is explained by assuming that the fibres of this bundle are particularly vulnerable and connect this vulnerability with its especially exquisite and delicate function, with which perhaps there is associated a correspondingly delicate anatomical structure. The more delicate a machine the more rapidly it is destroyed."

REPORT OF CASES.

CASE I.—January 22, 1921. Mrs. L. C., aged eighteen, no children, born U. S., occupation housewife, past history and family history negative, general health good. Present illness dated back three days only. Patient noticed a sudden diminution of vision in her left eye, which failed rapidly until three days previously, when she presented herself in the eye clinic at the Manhattan Eye, Ear and Throat Hospital for treatment.

Examination of the acuity of vision: OD=20/15. OS= failed to count fingers, light perception was present, pupil did not react to light and accomodation. Fundus examination was negative. Wassermann, uranalysis, and x ray of sinuses were ordered. January 25, 1921—three days later, vision OD=-20/15. OS= no light perception and no pupil reaction. Fundus, left disc less distinct in outline than the right; otherwise negative.

Blood and urine were negative x ray findings practically negative. Clinical examination of nose and throat showed a high deviated septum, otherwise normal. Dr. E. S. Thompson, our chief, advised opening the sinuses. His reason was that, in view of the seriousness of the condition exploration was justifiable.

She was operated upon January 26, 1921. Ethmoids and sphenoids freely opened, no gross pathological changes were found clinically.

The specimen consisted of several fragments of soft tissue and bone, sections showed ulcerations of the turbinate covering with dense infiltration of lymphocytes and polyps. The mucus glands were active and hyperplastic. The bone showed no distinct obliterations. Laboratory diagnosis chronic hyperplastic inflammatory tissue.

CASE II.—W. H., aged thirty-two, clerk in bank, past history and family history, negative. General health good, present history dated back to January, 1920, when he had an inflammation of his left eye which subsided in a few days, later noticing that the vision in his left eye was poor. An oculist refracted him with homatropine and found that the right eye was emmetropic and the left eye could not be corrected, informing him that his left eye was amblyopic.

June, 1920, about six months later, he noticed a blurring of vision which increased daily, compelling him to give up his position. He consulted a local ophthalmologist under whose care he remained for six weeks without any improvement. Wassermann and uranalysis were negative; x ray of the sinuses was reported clear. October 20, 1920 he consulted me with the history given above. Examination—OD pupil 4 mm. Reacted to light and accommodation, convergence poor, vision 6/200. OS pupil 3.5 mm. Reacted to light and accommodation, convergence poor. Vision 2/200. He said that his vision seemed clearer in the dark. Ophthalmoscopic examination—There was a slight pallor of the temporal side of the disc in both eyes, otherwise negative. Field.—An absolute central scotoma as shown by Fig. 3. No history of tobacco or alcohol. A diagnosis of retrobulbar neuritis was made. I advised another x ray, spinal Wassermann, and stool examination. Examination of stools was negative. He refused another x ray and spinal test. I then referred him for a neuro-

logical examination. Instead, he consulted a general surgeon for an occasional abdominal pain, who found a chronic appendicitis and advised removal which was done. January, 1921, he returned to me without his appendix, but his eye condition was much worse. Examination.—OD=fingers at ten feet not distinct. —OS fingers at six feet not distinct. The nerve much paler than on previous examinations. I referred him to the Neurological Institute for diagnosis and spinal test. The result was negative.

He was put there on eliminative treatment, but without any improvement. April 22, 1921, he came back and consented to have another x ray taken which was done at the Manhattan Eye, Ear and Throat Hospital.

X ray report—Frontals very large, with mild involvement. Ethmoid showed moderate involvement, no septa shown especially posterior, evidently an old process. Left antrum moderate involvement in the floor, Right antrum showed severe involvement throughout. Sphenoid large show moderate involvement.

May 5, 1921—A submucous resection and complete opening of ethmoids and sphenoids was performed. May 23rd—Vision OD=10/200, OS=8/200, June 14th—OD 15/200 with—100S=20/200 OS=15/200 with—75CX 180=20/200.

He said that he saw objects more distinctly and was able to recognize people in the street, which he could not do before operation. July 29, 1921—OD w-100S=20/200, OS w-75CX 180=20/100.

He read books of fine print and was very happy, because, as he said: "Considering that I could not read any print nor recognize objects, I appreciate the difference now." Field as shown in Fig. 4.

These two cases present a striking contrast for our consideration. In Case I. the patient was seen during an active stage which progressed within three days from seeing fingers to no light perception. Prompt operative interference gave immediate relief and complete recovery within a short time.

Case II. presents an entirely different picture. The acute stage probably occurred a year previous when the left eye was first involved. It was not of such an active nature. The right eye became involved seven months later, yet, after operation, the left eye, while of longer duration, had recovered more than the right. It is probable that the right optic nerve was more severely involved, hence atrophy occurred quicker than in the left.

While both nerves already showed signs of atrophy, the operative procedure was considered the only possible chance of saving any fibres not destroyed. That this step was justified was shown by the gradual subsidence of further activity in both eyes, especially the left one.

If this patient would have been operated upon at the time when the left eye was only involved, it is fair to assume, that he would have had as satisfactory results as the first case.

SUMMARY.

1. The striking feature in Case I. is the sudden onset of the visual disturbances and the rapidity with which complete blindness occurred and its equally rapid improvement after operation.
2. In Case II. the visual disturbances were rather gradual and at no time was there complete blindness, and the little improvement was equally gradual.
3. In both cases there was no visible evidence of diseases of the sinuses, yet opening the sinuses brought about prompt relief in first case and showed improvement in the second case.
4. In severe cases, the failure of sight may be very sudden, so that in a few days it may attain such a degree that all perception of light is abolished, as in Case I.
5. Central scotoma makes itself apparent to the patient by nyctolopia, hence, when a patient states that he sees better at night than in daylight always look for a central scotoma.
6. In cases of amblyopia, not due to errors of refraction, do not be satisfied until all possible causes have been excluded.
7. In retrobulbar neuritis cases which are not too far advanced, the sight can be brought back again to normal if the cause be promptly removed.

2915 MERMAID AVENUE.

Report of One Hundred and Four Mastoid Operations

By J. MORRISSET SMITH, M.D.,
New York.

The following report includes 104 mastoid operative cases just as they came under my supervision at the New York Polyclinic Hospital prior to its acquisition by the Government during the war. Of the total of 104 cases, seventy-two were acute and twenty-two chronic mastoid infections.

Included in the acute cases were sixteen subperiosteal abscesses, eleven of the acute infections showed a streptococcus mucosus capsulatus infection. Twenty-one of the total of the acute cases showed a perisinus or epidural abscess. No record was kept of the number of cases in which the sinus or dura was exposed by the operator—estimated about twenty-five per cent. In all of the acute infections, there was a thorough removal of the mastoid cells, the cavity was then swabbed with tincture of iodine followed by alcohol, the upper two thirds of the incision closed with clamps or silkworm gut, the wound was then packed with iodoform gauze. This routine was carried out when sinus or dura was exposed by the operator as well as in those cases showing a destruction of the dural plate by the disease.

Instead of leaving the wound open, it was partially closed but still enough of an opening maintained to allow it to be thoroughly cleansed at each dressing until the purulent secretion disappeared. The wound was then allowed to close. This answered the threefold purpose of shortening the convalescence, insuring safe healing and at the same time lessening the deformity.

The first complete dressing was done on the third day and the dressings repeated every day or second day thereafter until the healing was complete.

In all the seventy-two acute cases the patients recovered. There were three deaths in the twenty-two chronic infections; one from a temporosphenoidal abscess, one from a cerebellar abscess and one from a thrombosis of the lateral sinus followed by a double cavernous sinus thrombosis.

In nineteen of the twenty-two chronic cases radical mastoid operations were performed. There were no injuries to the facial nerve during the radical operation. In order that some definite idea might be obtained of the results following the radical mastoid operation, ten of the chronic cases were taken just as they presented themselves in the clinic; first examined and the hearing recorded, the radical operation was then done, a personal postoperative treatment carried out and the postoperative results with the hearing recorded. The whole series of ten cases were then presented before the Otological section of the New York Academy of Medicine. Nine of the ten were completely dry, one had a slight mucoid discharge from the eustachian tube. Eight of the ten showed improved hearing following the operation. For detailed report of the ten cases, see *Laryngoscope*, August, 1918.

Six of the nineteen radical cases showed a cholesteatoma; following a careful radical operation and removal of the cholesteatoma, all of the postauricular wounds were closed and there was no recurrence of the cholesteatoma in any of the six. One of the cholesteatoma patients was brought to the hospital in an ambulance in a semiconscious condition with a temperature of 104°F. and evidence of a beginning meningitis. Operation disclosed an enormous cholesteatoma with an extensive destruction of the dural plate in both the middle and posterior fossæ. Following a very extensive operation, he eventually made a complete recovery.

Two of the other cholesteatoma patients came in with high temperatures and symptoms suggesting meningeal involvement. Both made complete recoveries following radical operation.

Two cases which were not primary mastoid infections but were secondary to traumatic fractures of the skull are purposely omitted from the above series. For detailed report, see *Journal A. M. A.*, April 5, 1919.

The first of the three deaths was due to a temporosphenoidal abscess. The patient, man aged fifty-six, admitted to the hospital for observation. Chronic discharge left ear over twenty years duration. Examination showed destruction of drum membrane with a very scant but foul smelling discharge from region of attic. No definite symptoms were present upon which a diagnosis could be made but on sudden elevation of temperature to 103°F., operation was decided upon. Operation showed a complete bony sclerosis of mastoid structures, there being no cells present of any kind. Upon opening and enlarging the mastoid antrum, a small hole was found through the bony roof which apparently led into the brain in the midfossa.

Subtemporal decompression showed a tense dura and incision evacuated a large brain abscess, drainage was instituted but patient died two days later from a diffuse meningitis.

The second death was due to a cerebellar abscess. Female, aged forty-two, brought into the hospital in an ambulance with history of a mastoid operation at another hospital, several days previous. Severe headaches, insomnia, temperature 101° to 102.5°F.: spinal fluid negative. Conditions grew steadily worse and a diagnosis of brain abscess was made. Exploration of temporosphenoidal lobe negative. Exploration of cerebellum behind sinus negative. Patient's condition poor so time was not taken to explore cerebellum from in front of sinus. Patient died following day, postmortem showing small cerebellar abscess anteriorly which exploration from behind sinus failed to penetrate by the eighth of an inch. This shows the importance of an exploration anterior to the sinus when possible in all operations for suspected cerebellar abscess.

The third death was that of a boy, aged nine, with a double chronic aural infection present since infancy and showed the result of neglect in the chronic cases. Male, aged nine, ambulance case, temperature 104°F., mind hazy, partial Kernig present, foul smelling discharge and tenderness behind both ears. Immediate operation showed double cholesteatoma with large perisinus and epidural abscess, right side. Both mastoid cavities were drained, the diseased bone around the perisinus and epidural abscess removed, patient returned to bed. Temperature came down to normal with progress satisfactory until sixth day, when temperature suddenly jumped to 106°F. Blood culture positive, showing streptococcus present.

Due to the presence of a double infection, the lateral sinus was quickly exposed on the opposite side and found normal. The right sinus was then exposed and found completely clotted. The jugular was resected above the facial vein, the sinus then opened and free bleeding obtained from the torcular but not from the bulbar end. The patient was observed for four days; the high temperature continued, the wound was reopened, and the bone removed so the packing could be placed directly in the bulb. The infection extended into the cavernous sinuses and the patient died of a double cavernous sinus thrombosis, one month after the primary operation.

This patient had been to several clinics and given drops and nothing further advised and well illustrates the result which we may expect where they are neglected as he was. A radical operation advised sooner would have undoubtedly prevented the resulting intracranial complication.

RESULTS.

Total number of operations, 104. Total number of deaths, three—the death in each instance being due to an intracranial extension of the infection prior to the examination and operation by me.

25 West Fifty-first Street.

Massive Neoplasm of the Lung with Paralysis of the Diaphragm*

Recovery After Intensive Deep Röntgen Irradiation

By J. HENRY SCHROEDER, M.D.,
Cincinnati.

Contrary to every conception of the development of therapeutical processes, we find ourselves confronted, in the clinical application of intensive deep röntgen irradiation, with certain demonstrable results that cannot be founded upon experimental data. While these results must momentarily be accepted as clinical facts, in the course of time we may be able to draw clinical conclusions that will tend to establish a working basis for safe and effective clinical application of intensive deep roentgen irradiation.

I desire, therefore, to report a case of malignant neoplasm of the lung, in which prompt recovery of the patient followed the application of two socalled carcinoma doses of intensive deep röntgen irradiation. It will be apparent from the accompanying röntgenograms that this case lends itself exceptionally well to a demonstration of the pathological condition before treatment, as well as of the results accomplished by the röntgen irradiation. For obvious reasons a histological examination of the new growth could not be made. I am indebted to Dr. William Rienhoff, of Springfield, Mo., for the history of the case. He referred the case for irradiation and through his cooperation the continuous clinical record has been made possible.

Case.—M. C. B., the patient, referred on April 13, 1922, was a well preserved man, fifty-nine years of age. He stated that he had been in good health until shortly before Christmas, 1921, and his previous history suggested nothing of interest in connection with his present illness. Dr. Rienhoff's report was as follows:

"The patient was examined the first time in November, 1921, and again on April 4, 1922, when a decided increase in the morbid condition was noted. The loss in weight in that period had been about eleven pounds. The affected half of the right lung showed complete dullness on percussion and pronounced bronchial breathing on auscultation. There had been little expectoration, an occasional feverish temperature toward evening, and shortness of breath, quite intense upon slight exertion. The sputum, such as could be obtained, did not show any tubercle bacilli. The complement fixation test for tuberculosis was negative, as was also the Wassermann test. The blood examination showed only secondary anemia. The röntgenogram (Fig. 1) shows a well circumscribed, deep shadow, quite extensive, on the upper half of the right lung, apparently affecting the upper lobe and part of the middle lobe. Under fluoroscopic examination there was a noted marked contrast in the respiratory expansion of the sound left side and the affected right side. Therefore, a diagnosis was made of pulmonary tumor, and under the existing circumstances it was probably of a carcinomatous character."

I made an examination of the patient at the time of his first treatment on April 14, 1922, which confirmed Dr. Rienhoff's observations. The patient stated that he coughed only moderately. The surface lymphatic glands were not enlarged. There was very limited chest expansion on the right side and no evidence of pleural exudate. Nothing abnormal could be detected on the part of other organs.

At that time stereoscopic lung plates revealed a dense infiltration of the parenchyma of the upper half of the right lung (Fig. 1), fusing with clearer lung tissue of the lower part of the lung. The marked peribronchial infiltration just below the mass is strikingly shown in the röntgenogram, which also revealed the elevation of the right side of the diaphragm. Fluoroscopically the diaphragm on that side was found to be immobile. The paralysis can be accounted for by the almost inevitable compression of the phrenic nerve above. The larynx was not distorted. The condition admitted therefore of a direct diagnosis of neoplasm of the lung, with secondary paralysis of the diaphragm on the involved side. The condition of the patient indicated the malignant character of the new growth. I undertook the irradiation because of the still comparatively good physical condition of the patient that promised good resistance.

On April 14, 1922, I administered the minimum carcinoma dose of Wintz, that is, 100 per cent. of the surface erythema dose of the ultrahard röntgen rays at 200,000 volts maximum, to the tumor mass in the lung, in one treatment. I used one large area of entrance anteriorly and one posteriorly, corresponding in extent to the easily demonstrable area of lung involved. In order to maintain a maximum effect I administered seven days later an additional thirty per cent. of the carcinoma dose through an available area that had not been exposed during the first irradiation.

The systemic effect of the irradiation was mild. The evidence of lung irritation—increased cough and tightness in the chest—became evident in twenty-four hours and subsided in the course of a week. The surface irradiation erythema was mild. With the subsidence of the systemic reaction the patient's condition improved visibly. He had gained two and one half pounds in weight ten days after the irradiation, when he departed for his home in Springfield, Mo., and again came under the observation of Dr. Rienhoff.

Dr. Rienhoff reexamined the patient on May 23, 1922, about six weeks after the first irradiation dose. His report follows:

"1. The general subjective condition has decidedly improved. The patient feels better, is stronger, able to walk any distance, any length of time, and up and down stairs without getting tired or short of breath. The cough has entirely disappeared. The appetite is excellent.

---

*Accepted for publication in February, 1923.

"2. Objectively, his general appearance has changed, he has good color and a bright expression. His weight, which had come down to 152 pounds, has come up to 154½ pounds. His pulse is 72, full and strong. The temperature has been normal throughout the time after his return.

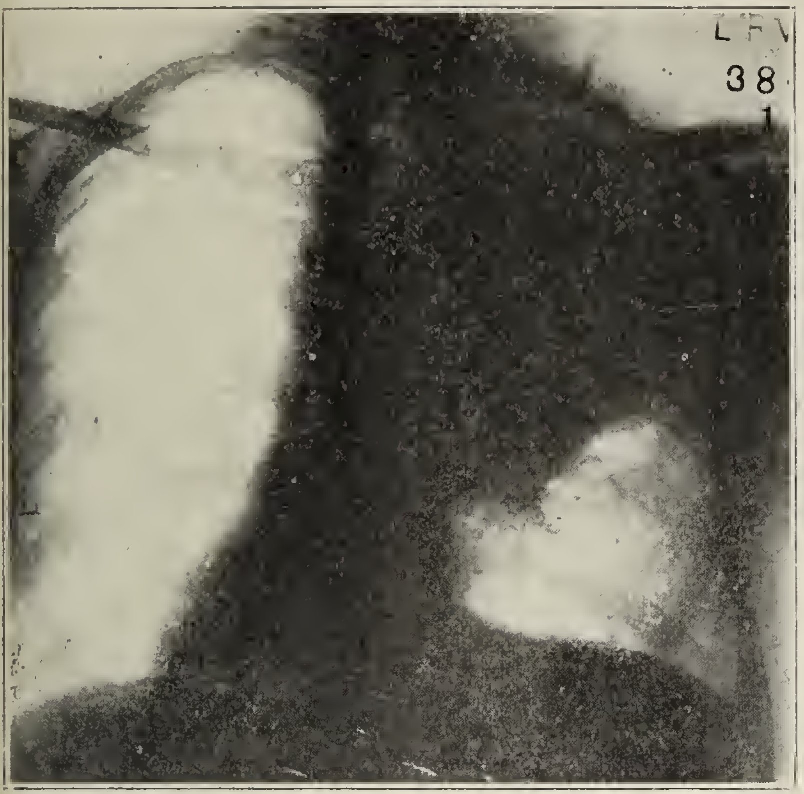

Fig. 1.—Lung before röntgen irradiation, showing extent of tumor, the marked peribronchial infiltration of adjoining lung tissue and elevation of diaphragm, right side.

"3. The extent of dullness on the right side has decreased, and so has the area over which the sonorous bronchial breathing was so distinct. There is a space over which distinct vesicular breathing is to be heard, covering a small portion of the upper right lung, laterally to the dull part.

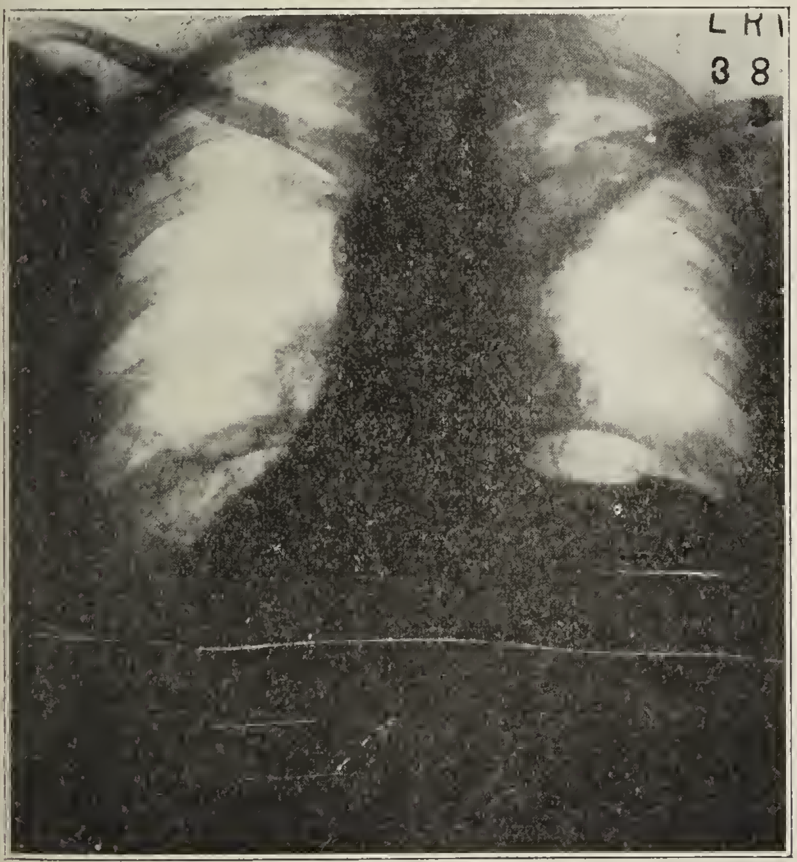

Fig. 2.—Lung six weeks after first röntgen irradiation dose, showing marked retrogression of tumor, diaphragm paralyzed.

"4. The shadow in the upper right lung as shown in the radiogram (Fig. 2), when compared with the intensity and extent of the former picture, speaks for itself. The expansion of the right lung, however, as shown in the fluoroscopic examination, is still quite limited. In fact, the movement of the diaphragm on the right side is almost nil. It appears as if there must be a disturbance, possibly a compression of the phrenic nerve, near the entrance to the thoracic space.

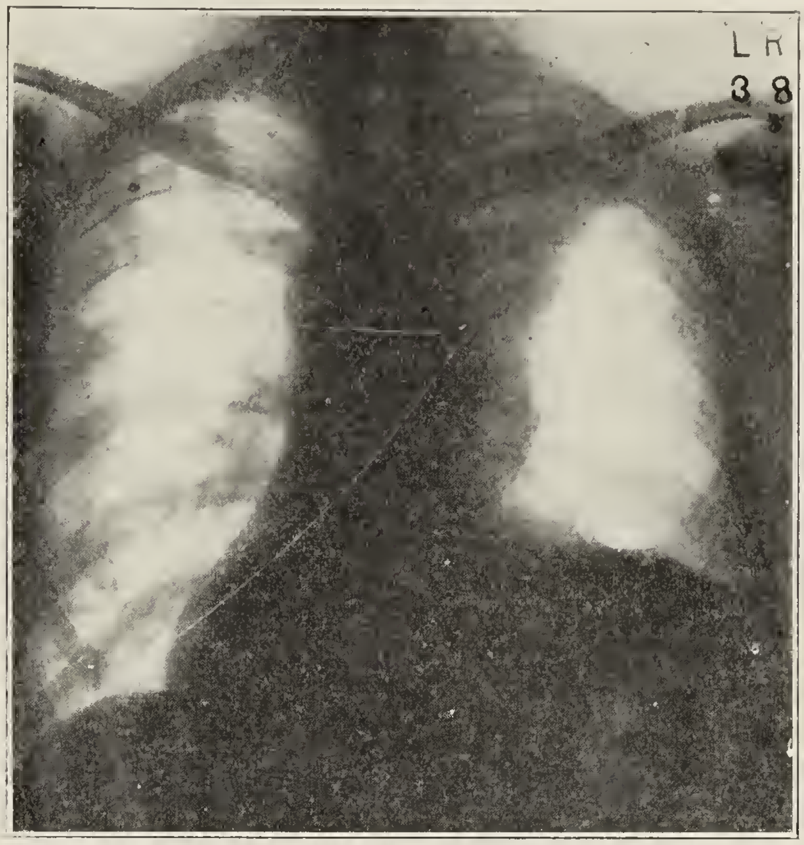

Fig. 3.—Lung about six weeks after second röntgen irradiation dose; further retrogression of tumor. Diaphragh still paralyzed.

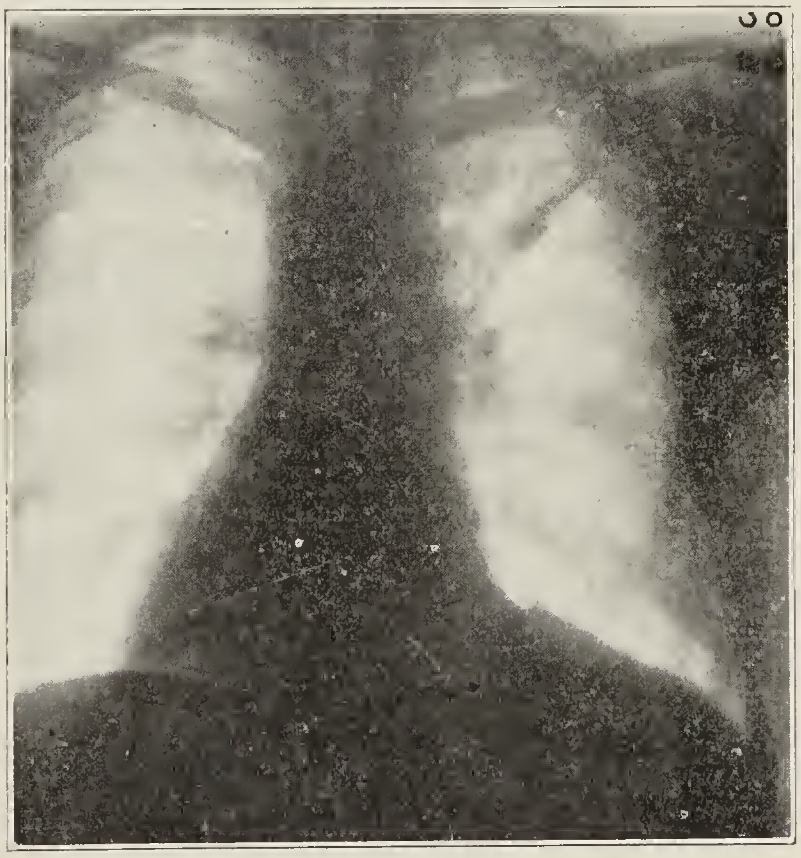

Fig. 4.—Lung four months after second röngten irradiation. The neoplasm has disappeared and the paralysis of the diaphragm has subsided. The area formerly involved by the neoplasm shows apparently a slight connective tissue proliferation.

"5. No trace of exudate could be found.

"6. Nothing abnormal could be detected in any other organ or tissues."

It will be noted that the tuberculosis complement fixation test before the irradiation was negative; after the intensive röntgen irradiation it was reported two plus positive. I am informed that only a two plus fixation test for tuberculosis under such circumstances may be accounted for by a protein disturbance through an absorption of tumor constituents after the irradiation.

I administered the second dose on June 6 and 9, 1922. The technic was the same as that described above, with this difference, that in order to obtain in the greatest degree a homogeneous radiation dose throughout every part of the tumor tissue, separate doses of 100 per cent. of the Wintz units were administered to the upper portion of the tumor and to the lower portion, including the hilus region, three days apart.

The immediate effects were the same as those recorded after the first irradiation dose. The röntgenogram of July 27, 1922 (Fig. 3), shows the retrogression of the tumor mass, but the diaphragm is still paralyzed.

Dr. Rienhoff reported under date of August 10, 1922: "The condition of Mr. B. is excellent. . . . None of the former morbid symptoms are noticeable, except the objective physical signs in the small area revealed by the x ray plate." (Fig. 3).

The last roentgenogram (Fig. 4), made on October 12, 1922, reveals the lung free from evidence of the former tumor, and the paralysis of the diaphragm has disappeared. There is noticeable in the formerly involved area an increased density that suggests connective tissue proliferation (to which I shall refer in my comment).

A final fluoroscopic examination was made by Dr. Leslie R. Webb, of Springfield, Mo., on November 15, 1922. His report is as follows:

"Both lungs inflate equally. Hilus shadows increased in both lungs. Right apex slightly more dense than left, with shadow extending from about two cm. below the clavicle in outer border of apex to six cm. below clavicle internally. Ribs move through normal excursion during inspiration. Diaphragm moves through normal excursion during inspiration and expiration, each side moving equally, left and right side in normal proportion. Costophrenic angle clear. Cardiophrenic angle clear."

Under date of October 13, 1922, and again on January 22, 1923, Dr. Rienhoff reports:

"Mr. B. is apparently perfectly well. He has no complaint to make of any kind. He works as much and as vigorously and with as much ambition as ever. There is no respiratory impairment whatever. His weight is 168 pounds. That represents a gain of sixteen pounds since the first irradiation."

The problem of safe and effective roentgen irradiation of the lung is the problem of resistance and reaction of lung tissue, under pathological conditions, to the absorbed radiation. The effect of the required röntgen radiation doses upon lung tissue must obviously determine our recourse to, and the applicability of, this form of treatment. Clinically, it is the effect upon lung tissue under pathological conditions. Experimental data are not available, and indeed, it seems difficult to conceive of a plan of systematic research in this field under clinical conditions.

In place of logical development of the problem there stand forth bluntly two demonstrated facts:

1. Hines (1) has made a valuable report of a case of spindlecelled sarcoma of the lung which was subjected to röntgen irradiation; the radiotion dose was not stated. The patient was given three applications in the course of four months. During the last series of treatment respiratory distress developed, and several days later death occurred. Necropsy and histological examination revealed an extensive fibrosis. "All parts of the lung were consolidated from proliferation of connective tissue in the alveolar walls, with resultant great decrease in air space, which accounts for the dyspnea and cyanosis, and might be considered as the immediate cause of death."

2. The case which I have reported here, as well as a case that I previously demonstrated (2), wherein both lungs were effectively and safely irradiated for diffuse secondary sarcoma, proves that under certain conditions two successive sarcoma doses and two successive carcinoma doses, as stated, were not followed by a pathological fibrosis of the lungs, but were therapeutically effective and resulted in the immediate recovery of the patient.

One might reasonably expect some proliferative connective tissue reaction after the absorption of large doses of röntgen radiation by pathologically altered lung tissue, either as a primary reaction to the irradiation, or as the result of retrogression of tumor masses, or both. It is logical to assume that the degree of such a reaction would vary with the radiation dose and the nature of the pathological involvement of the lung tissue. I have been able to demonstrate in the sarcoma case, referred to above, that two sarcoma doses applied to the lung with an interval of six weeks, did not give rise to a recognizable röntgen fibrosis even after the complete retrogression of the tumor mass. A reexamination on February 1, 1923, one year after the irradiation, revealed the lung still entirely free from recurrence of tumor and any tendency to fibrosis.

In the case reported here, where I administered two carcinoma doses, that is, thirty per cent. greater than the sarcoma dose, I find that I advised the patient's physician at the time of the first irradiation of the probability of a subsequent connective tissue proliferation in the involved and irradiated area. Judging from the final röntgenogram, after the irradiation and the fluoroscopic examination, this anticipated connective tissue proliferation has in fact occurred, not as a pathological fibrosis, but seemingly as a biological phase in the reaction of the tissues to radiation doses of that degree, and retrogression of pathological tissues.

Intensive röntgen irradiation of one half of one lung involved by a malignant neoplasm, with two successive carcinoma doses, resulted in the disappearance of the tumor. It was followed by a recognizable increase in density, as revealed by röntgen examination, which resembled in appearance a connective tissue proliferation in the formerly involved area. There are no manifestations of reduced air capacity, and the patient is apparently well.

The Neurological Phase of Otology*

A Simple Presentation of the Bárány Tests

By MERVIN C. MYERSON, M.D.,
Brooklyn.

The neurological phase of otology embraces a science in itself, the science of neurootology or otoneurology. This science is of value to the medical man in general because of his occasional or frequent encounter with patients complaining of vertigo, and to the neurologist and the neurological surgeon in particular, because of the connections between the internal ear and the various intracranial centres which communicate by their fibres with the entire body. Physiological experiments on the semicircular canals were performed by Flourens in 1828 and continued by Goltz, Crum-Brown, Breuer, Ewald, and others. In the past fifteen years Bárány, particularly, has placed the knowledge and findings of these various workers on a practical basis, and a science has been elaborated which has a recognized place in medical diagnosis. In this country Shambaugh, Friesner and Braun, Mills, and Jones and Fisher, have contributed to our knowledge of this subject.

It has been established that the internal ear has, in addition to its auditory function, a mechanism concerned with the appreciation of position in space and the maintenance of equilibrium. That portion of the internal ear which is concerned with equilibrium is known as the vestibular apparatus or labyrinth. This consists of a vestibule and three semicircular canals. Each canal contains within its membranous interior a fluid, endolymph, and has an ampullated end which lodges a sensory end organ, the crista. Motion of the endolymph in one direction or the other, within the canal, stimulates the nerve filaments in the crista and sends forth an impulse from it; the type of impulse varying according to the direction of the flow of endolymph. It is disturbances of these endorgans, singly or collectively, that cause disturbances in the function of the labyrinth which may show themselves spontaneously as nystagmus and vertigo, at times associated with nausea and vomiting. Artificial stimulation similarly will produce disturbance of these endorgans and cause nystagmus and vertigo. Nystagmus is a twitching or rhythmic jerking of the eyes in a given direction. Vertigo is a lack of appreciation of one's position in space due to a disorder or disharmony of the impulses that tend to maintain equilibrium.

Impulses are constantly going to the eye muscles to preserve their normal balance relationship. This normal balance relationship is disturbed by disease or by artificial stimulation of the labyrinth and this disturbance is recognized as nystagmus. In a like manner impulses are traveling from the vestibular apparatus to the muscles of the body to maintain their tonus; this is borne out by the fact that disturbance of the labyrinthine function will produce vertigo and falling. Ewald demonstrated that animals in which the labyrinth has been destroyed, show a lack of tonus of the body muscles.

In the consideration of vertigo produced by labyrinthine lesions, it must be remembered that the sense of touch, visual impressions, and impulses from the muscles, joints and tendons, help to preserve body balance. These perform the function of the static labyrinth when it is destroyed, but do so very poorly at first, because as Friesner explains: "The centres in which all these impulses are gathered, accommodate themselves to the loss of the normal influences of the static labyrinth, and a compensation results." Because of this new conception of vertigo, and because it is registered within a definite part of the brain, such terms as gastric vertigo, renal vertigo, or cardiac vertigo are considered erroneous. All vertigo is due to an involvement of the internal ear or its intracranial pathways, which constitute the apparatus responsible for vertigo. The stomach, heart or kidney produce vertigo, not directly, but by their influence upon the labyrinth or its pathways.

Where vertigo exists, frequently nausea and vomiting may also be present. This is true of vertigo artificially produced or produced by disease. Nausea and vomiting are produced by the spreading of an abnormal impulse from the vestibular nerve nucleus to the vagus nucleus which lies close by.

Special tests have been devised for establishing the integrity of the vestibular apparatus, and for diagnosing disease of it. These tests consist of: The turning or rotation test, the douching or caloric test, the galvanic test, and the fistula test.

The galvanic test consists of stimulation of the labyrinth by a galvanic current. The fistula test consists in the compression or aspiration of air in the external auditory meatus in the presence of a fistulous opening somewhere in the labyrinth. The most practical and most universally applied tests are the turning and douching tests.

For the turning or rotation tests[1] the patient is placed in the Bárány chair or its modification and turned a given number of times at a given speed. The head is placed at an angle which will bring the canals to be tested in the horizontal plane. With a given normal stimulus, such as the turning produces, the labyrinth reacts in such a way as to create a normal response in the phenomena of nystagmus and vertigo. A normal response indicates that the labyrinths are functioning normally and the tracts responsible for the responses are intact.

The caloric test consists of douching the ear with cold water at 70° F. or hot water at 110° F. This douching has an advantage over the turning in that a single labyrinth can be examined at a time, whereas in the turning both labyrinths are tested simultaneously. The impulse which is generated in the semicircular canals is due to the current set up in the endolymph when it is cooled or heated. The cooler portion of the endolymph is constantly seeking a lower level. This is the cause of the endolymph movement. The normal nystagmus and vertigo which result from this test are indicative of a normal labyrinth and intact pathways. Abnormalities in reaction are interpreted as abnormalities in the labyrinth or the pathways.

---

*Read before joint meeting of Brooklyn Neurological and the Flatbush Medical Society, February 9, 1923.

In addition to nystagmus and vertigo, reaction movements are produced as a result of stimulation. These reaction movements are always present when vertigo is present, and are considered a secondary manifestation of vertigo. Reaction movements, according to Bárány, are voluntary movements in the extremities or body, arising in the cortex which are modified in the cerebellum by impulses from the semicircular canals. If the impulses are not forthcoming from the canals, or are intercepted by a break in the pathways, or are abnormal because of the impaired function of the canals, the movements will be influenced accordingly. To elicit reaction movements of the extremities the past pointing test is employed; for the body the falling test is used. A normal person can touch a fixed point with his eyes closed when told to do so; whereas, after his labyrinth has been stimulated, he will not be able to touch the fixed point, but will point past it. The falling test is evidenced by the reaction of falling when any of the canals have been stimulated in a vertical plane. These tests prove the influence of the labyrinth upon the cerebellum in respect to coordinated or synergistic motion. These tests and the reactions which result therefrom demonstrate the following facts:

There is a connection between the semicircular canals and the eye muscles in the production of nystagmus. There is a connection between the semicircular canals and the cortex in the production of vertigo, for vertigo is a conscious phenomenon, and therefore cerebral. There is a connection between the semicircular canals and the cortex of the brain, by way of the cerebellum in the past pointing and falling reactions. That there are reaction movements for the extremities in the pointing test, and for the trunk in the falling test. This means that the impulses from the labyrinth can influence any part of the body.

The pathways from the labyrinth to the eye muscles are well known. The pathways between the labyrinth and the cerebellum, and the joints and muscles and cerebellum, and between the cerebral cortex and the cerebellum have been carefully worked out.

An examination of the labyrinth by the tests described furnishes us with definite information, in that they do or do not produce nystagmus, vertigo, past pointing, and falling. The production of these reactions are dependent not only upon the normal condition of the vestibular apparatus from which the impulses emanate, but also upon the integrity of the pathways from the labyrinth to various centres within the brain which preside over or influence these responses. As a result of this, the otologist can localize lesions that might involve the pathways from the labyrinth. As our knowledge of this relatively new science increases, the ability to localize intracranial lesions will increase, and this form of examination will become indispensable. Of conditions that involve the associated pathways, lesions have been localized in the cerebellopontine angle, the medulla, the pons, the cerebellar peduncles, and various parts of the cerebrum. At the present time, however, it would seem that these neurootological examinations do not promise the accuracy in diagnosis of intracranial lesions that has been asserted for them. Instances of an absence of neurootological findings in the presence of intracranial pathology which was demonstrated at autopsy or on the operating table have been reported. It would seem that a good deal more must be known before a series of infallible tests will be elaborated, if such is possible.

I have found these tests of particular value in cases of suspected malingering where deafness and vertigo follows head injury. The Barany tests have made of vertigo a true clinical entity. It must be borne in mind that the normal internal ear and its normal associated pathways keep the individual from having vertigo. A disharmony, or disbalance in the impulses emanating from the labyrinths, whether due to labyrinth disfunctions, or disturbance along the pathways to the intracranial centres, causes vertigo.

The otologist can assist in the diagnosis of cases of vertigo by establishing whether a lesion exists in the ear itself or in the pathways from the ears. In the internal ear we may have the effects of toxemia, hyperemia, anemia, or involvement of any degree due to a suppurative lesion. Of toxemias which affect the internal ear mechanism, the most severe are those of syphilis and mumps, while the most frequent are those from a focus of infection.

The following cases are reported to demonstrate the value of these tests:

CASE I. A. P., male, aged forty-seven, was referred by an internist June 13, 1922. His chief complaint was recurrent attacks of vertigo, which were associated with nausea, and had been occurring for the past six weeks. His attacks shortly before he presented himself, had been occurring every two or three days, until in the past few days they were coming on daily. These attacks had become so violent as to prevent his leaving his bed for two or three hours every morning. The patient associated his illness with his gastrointestinal tract because of his nausea. He was referred to the internist because of the suffering he experienced as a result of these attacks, during which he felt very much alarmed. The following is the report of the findings in this case, as submitted to the doctor who referred him:

"The history gives no evidence of a severe toxic factor that may have impaired this patient's vestibular function, such as mumps, syphilis, scarlet fever, etc."

Turning tests produced delayed and diminished reactions in nystagmus, vertigo and past pointing, indicating on the one hand, the integrity of the intracranial pathways, and on the other hand, almost a complete destruction of the labyrinths or eighth nerves (vestibular portion). Douching after four minutes gave very slight reactions. This is indicative of little function still remaining.

The otoneurological examination suggests an almost complete destruction (impairment of function) of both labyrinths or eighth nerves. A general toxemia of virulent type such as syphilis, is probably the only thing that could account for the findings which this man presents. His vertigo is due to the unequal projection of equilibratory stimuli going from the labyrinth on either side. This examination has definitely ruled out brain stem or intracranial pathway neoplasm. The nausea of which this patient complains is due to the stimulus spreading to the vagus nucleus from the vestibular nucleus whenever his disordered vestibular function asserts itself. The prognosis for eventual cessation of vertigo is good. Without antiluetic treatment this patient will continue to have vertiginous attacks until there is a total destruction of both labyrinths or eighth nerves. With antiluetic treatment there should be a gradual improvement and cessation of this distressing condition.

The diagnosis was rendered as a luetic involvement of the vestibular portion of each eighth nerve, with some involvement of the cochlear portion also. This report and diagnosis were rendered after the blood Wassermann had been reported negative and there was nothing in the history or physical findings to suggest syphilis. Upon receipt of the opinion above, the internist gave the patient an injection of mercury salicylate and placed him on fifteen grains of potassium iodide three time a day. There was almost an immediate cessation of symptoms after the mercury injection. The patient received another similar injection a few days later and passed out of sight for several months. He returned complaining of slight attacks of vertigo and was immediately given treatment similar to that mentioned above. He refuses to have salvarasan given him, and will not permit a lumbar puncture. He has steadfastly denied a luetic history.

The vestibular branch of the eighth nerve may be early involved in cerebrospinal syphilis, and this case is an example of the early diagnosis of that condition by these special tests.

CASE II. J. F., male, aged thirty-two. Was referred October 20, 1921. He gave a history of frequent attacks of vertigo over a period of six weeks. When perfectly quiet and with his head at rest he experienced no dizziness, but any sudden change of the position of the head would cause distressing vertigo, so that he could not carry on his occupation of ice dealer. Both turning tests and douching demonstrated an impaired function in the right labyrinth. The left labyrinth was found to react normally in all respects. A diagnosis of toxic labyrinthitis was made. Examination revealed as the most probable cause of this disturbance several infected and carious teeth, especially two or three in his left upper jaw. The patient did not take kindly to the suggestion that he have his teeth cared for, and was not seen for about three months. He returned to inform me that a few weeks after his last visit he had broken two of his upper teeth and was forced to have their stumps extracted. His vertigo left him almost immediately after the removal of these roots and he had felt perfectly well since.

Case III will appear in the author's reprints.

A Survey and Interpretation of the Spastic Phenomena of the Gastroenteric Tract

By M. GOLOB, M.D.,
New York,
Assistant in Gastrointestinal Diseases, Vanderbilt Clinic, Columbia University; Department of Gastrointestinal Diseases, The Bronx Hospital.

Stockton (1), discussing the spasms of the esophagus, classified them as to duration: those that are temporary or transient, and those that are persistent and progressive. As it is my intention to survey the entire gastrointestinal tract with a view to presenting its spastic phenomena in terms of the symptomatology of the diverse maladies from which they are derived, I believe that a classification based on location will be more suitable for this paper. The spasms of the gastrointestinal tract, then, will be discussed in their anatomical order, downward, namely: cardiospasm, gastrospasm, pylorospasm, duodenal spasm, and enterospasm.

A brief, preliminary review of the nervous mechanism of the primæ viæ is essential. The innervation of the esophagus is derived from the vagus and from the sympathetic. The stomach is likewise innervated by the cerebrospinal system, and the sympathetic; with the former through the medium of the vagi; with the latter by the splanchnics through the solar plexus. The nerve supply of the intestines differs, however, as it consists mainly of nerves from the sympathetic system with a few filaments from the vagus, and in addition of an autonomic system comprised of the ganglia of Auerbach and Meissner —those of Auerbach residing between the muscular coats, and those of Meissner in the submucosa; and both belonging to the sympathetic system (2).

Reverting to the esophagus, it is worth mentioning the fact that normally the esophagus has five points of constriction, namely: at the introitus, at the aortic arch, at the crossing of the left bronchus, at the hiatus esophagi, and finally, at the cardiac opening (3). The entire epicardia, that is, the portion of the esophagus below the diaphragm, is distinctly narrower than the rest of the esophagus.

When the presenting symptom is dysphagia the question arises whether we have a spastic manifestation due to a neurosis, or a symptom of structural pathology. If the former, we should usually have as an accompanying symptom a complaint of substernal soreness brought about by certain articles of food which adhere, when swallowed, to the interior of the esophageal wall. A history of long duration would complete the triad of symptoms of an esophageal neurosis.

This form of malady, if allowed to persist, may be the precursor of the much more serious structural pathology of cardiospasm, socalled because the contraction is at the terminal end of the esophagus. This phase of the spastic phenomena furnishes a noteworthy instance of a structural change brought about by overactivity. The mechanical influences which obtain here are not unlike those of a cardiac lesion. In the mechanism of the latter a marked hypertrophy is attended with a secondary dilatation which soon predominates over the hypertrophy. In the cardiospasm a marked dilatation of the esophagus is associated with an unusually strong constriction of the cardiac sphincter and hypertrophy of unusual degree and long duration. Apropos of this I cannot forget the words of James Anders: "In obedience to the laws of nature, over use of any single group of muscles, while productive of marked hypertrophy in the first instance, is followed eventually by atrophy and loss of power."

A distinction has been drawn by Smithies (4) between cardiospasm and spasm at the cardia. Only the former affection includes hypertrophy at the cardiac sphincter with general diffuse dilatation of the esophagus. The spasm at the cardia is but a transient spasm with no accompanying dilatation; unless it be of such duration and persistence as to produce esophageal changes not of a transient character. At this point, it has ceased to be a spasm at the cardia, but has developed into a cardiospasm.

Fluoroscopically, these conditions are differentiated by recourse to the administration of such antispasmodics as belladonna, atropine sulphate, benzyl benzoate, to the point of physiological response, to which cardiospasm does not yield.

Spasm at the cardia may be induced by psychic storms and is therefore prevalent in individuals of the hypersensitive type. An approximation to the nervous status of the patient can be obtained by the method devised by Emanuel Libman, consisting of making firm pressure over the processes of both temporal bones simultaneously. In the hypersensitive individual one can elicit a marked reaction in the form of a contraction of the facial muscles, significant of pain; while in the hyposensitive patient this response is hardly noticeable. Thus we see that the etiological factors concerned in inducing spasm at the cardia may produce a more intense response when operating upon the type of individual that is neurologically excessive in reaction. As cardiospasm is a distinctly anatomical condition, in ascertaining the sensory status of the patient there is not elicited any expression of pain, unless there be also associated a state of psychoasthenia.

Smithies (4) points out that where liquid foods are quicker to provoke distress than are solids, a type of dysphagia is presented, which is a fairly characteristic diagnostic sign of cardiospasm. The tendency among practitioners to prescribe a liquid diet in such cases has not infrequently led the patient to express a preference for solids because they are better borne. In this respect this type of dysphagia differs strikingly from that common to various forms of anatomical stenosis (ulcer, cancer, trauma, etc.) along the course of the esophagus.

It may here be well to refer to the röntgenological signs of the pathological conditions of the esophagus, varying from an indication of a mere hesitation or delay of the opaque meal at the cardia to a total stoppage. The radiographic shadow appears as a regularly conical obstruction at or near the cardia, with a secondary dilatation above it. Though quite different this must be distinguished from the shadowgraph seen in a carcinoma of the lower esophagus. Here, stenosis is not limited to the hiatus esophagi, but almost always ascends above the diaphragmatic orifice; and usually, the lower end of the barium shadow "tails out irregularly." Moreover, cardiospasm and malignancy at the cardia can be further differentiated röntgenologically by the following sign complex of the latter: 1, delayed esophageal evacuation; 2, distortion of the gas bubble; 3, distortion of the cardia, and 4, elevation of the left diaphragm. Dilatation is conspicuously absent in malignancy, except for a slight dilatation above the point of constriction. It is syphilis, and more particularly cardiospasm, that gives a markedly dilated esophagus.

We will now pass to a consideration of the various spastic phenomena observed in both functional and organic disturbances of the stomach. The phenomena collectively spoken of as a gastrospasm differ vastly in their behavior, depending upon whether the underlying factor is functional or organic, extrinsic or intrinsic.

The stomach has been properly alluded to as the playground of spasm and excitement, and is the site of conflict whether the disturbing factor be endogenous or exogenous. It is not a static organ passive in vocation—a mere chemical retort—but a functionating dynamic apparatus sensitized to respond to stimulus from any source. To emphasize this diversity of sources Heyd (5) summarized a hundred cases. In twenty per cent. the etiological and provoking factors were in the form of organic disease of the stomach; in forty per cent. the lesion was within the abdomen, but remote from the stomach, and in the remaining forty per cent. the pathological process resided entirely without the abdominal cavity.

A principal source of external irritation provocative of gastrospasm lies in the nervous mechanism of the vagus and the sympathetic, together with their relay stations. If for some reason the vagotonic group be disturbed, any one of a diversity of conditions may arise (6): cardiospasm, pylorospasm, vomitus nervosa, regurgitation, hyperchlorhydria, hypersecretion, bulimia. Likewise, in accord with its function, a disturbed sympatheticotonia results in diminished activity of the gastric functions, inducing such conditions as incontinence of the cardia and pylorus, atony of the stomach, and diminished secretion—in short, a quiescent, fatigued stomach—the whole picture spelling passivity.

Not so apparent, but none the less persistent in its influence on the gastrointestinal nervous apparatus, is the effect engendered by disturbance of the endocrine glands. In his study of endocrinology, Garretson (7) declares with emphasis that the sympathetic of the vegetative nervous system is activated and maintained in balance by adrenalin, the hormone of the suprarenals; while the autonomic portion is dominated by the posterior lobe of the pituitary gland. It follows that a state of hypoadrenia or suprarenal insufficiency with its attendant manifestations, such as low blood pressure and impoverished sympathetic tone, allows of the unimpeded action of the vagus, which, unrestricted, inaugurates a condition of vagotonia with its sequelæ—hyperchlorhydria and hypersecretion. On the other hand, hyperfunction of the suprarenal glands is productive of sympathicotonia, in which a reverse clinical picture is observed. Garretson also singles out for attention that hypopituitarism produces a lowered vagal tone with resulting sympathicotonia, while hyperpituitarism creates vagotonia. Does it not become apparent that the therapeutic indications in the treatment of gastrointestinal functional conditions may largely depend upon the deduction that gastric symptoms arising from certain endocrine disturbances may yield to attempts to induce a compensatory stress reaction of the thyroid, which would take off the load from the overactive pituitary? Or, from the viewpoint of drug therapy it therefore materially differs whether we will administer atropine to paralyze the vagus so as to cause a cessation of gastric secretion; or give adrenalin to stimulate the sympatheticus so as to inhibit the gastric flow.

A case in point is that of S. G., aged forty-five, weighing 192 pounds, presenting these symptoms of vagotonia: persistent systolic pressure of 110, increased salivary secretion, slow pulse, thus a hypoadrenia with its attendant hypotension and hyperchlorhydria; free hydrochloric acid 50, total acidity 90. Under the administration of suprarenal extract, the symptoms disappeared and the blood pressure rose to 120, and gastric analysis showed a lowered gastric titre.

Kaplan (8) asserts that "too meagre a supply of adrenalin secretion permits the hydrochloric acid to be formed in pathological quantities," and cites two cases where suprarenal extract administered in small doses showed in one case, as a result of one month's treatment a reduction of total acidity from 108/40 to 88, and of free hydrochloric acid from 78/40 to 46; in the other case, after six weeks' treatment, a reduction in total acidity from 142/40 to 98, and in free hydrochloric acid from 86/40 to 50.

In interpreting symptoms that arise from gastrointestinal disturbances, Meltzer's (9) law of contrary innervation presents an acceptable explanation of some of the spastic phenomena, and may therefore be applied with advantage. The law, in brief, is based on a physiological phenomenon, by which a viscus is innervated by two antagonistic sets of fibres, namely those of inhibition and those of contraction, working simultaneously. Meltzer applies it in defining intestinal and gastric colic. He states that if the caudal end of the viscus remains contracted while the cephalic muscular fibres are contracting and progressing forward, there results a progressive diminution in the volume of the viscus between the points of contraction, without any reduction of contents, thereby producing extreme tension and the sensation of colicky pain.

Also in the case of the gallbladder, a disturbed innervation which fails to relax Oddie's muscle while the gallbladder is contracting, results in biliary colic and stasis. And pylorospasm may ensue through failure of the neutralization of the acid chyme by the alkaline bile.

An indispensable aid in the diagnosis of spastic phenomena of the digestive tube is the röntgenological study of the passage of an opaque meal. A word of caution here may be timely. Spasm of any sort, whether it be remote from its source or of intrinsic causation, vanishes under the influence of deep narcosis. It is therefore advisable when confronted with such spastic manifestations as the incisura, or hour glass contraction or pylorospasm, to administer an antispasmodic to the point of physiological action, and thereby produce relaxation. Failure of the spasm to relax would indicate an intrinsic cause, such as a gastric ulcer, and its shadowgraph record would serve to remove any doubt that may arise because of the disappearance of the spasm through narcosis.

Interpretation of the röntgenological findings must be dominated by a sense of fitness. By way of illustration of what I mean, let us assume that the patient is of the apoplectic habitus, that is, the hyperesthenic type. A röntgenological confirmation would lie in finding a stomach of the hyperesthenic type, rapidly active antrum, good tone, and active or hyperperistalsis. If, however, the stomach should prove to be of the atonic type, with delayed evacuation, delayed peristalsis, then we must assume a pathological condition. On the other hand, the atonic type of stomach is normal in the asthenic habitus.

It almost goes without saying that in the study of spastic phenomena, the x ray findings are not sufficient by themselves, but must be supplemented by and interpreted in the light of accompanying clinical and laboratory tests. For instance, from our laboratory data we know that ulcus is a weeping disease in contrast to malignancy, which is dry. The corresponding symptom complex under x ray is hypersecretion, hyperperistalsis, with gastrospasm as a standing phenomenon. In the case of malignancy the symptom complex under x ray is analogically the reverse: presenting diminished secretion, diminished peristalsis of the uninvolved part, with absence of peristalsis at the site of infiltration—in short, a quiescent stomach. But where, for example, the malignancy has infiltrated the stomach wall, the röntgenograph, in failing to disclose a filling defect, tends to mislead, unless checked and interpreted by clinical study.

We know that the factors concerned in carrying on the normal pyloric patency, which is intermittent, are the interplay of the acid chyme and the alkaline secretions of the duodenum. The pylorus is opened by the action of the acid chyme upon the mucous membrane lying proximal to it, and is closed when the alkaline secretion of the duodenum mixes with the acid chyme and effects its neutralization. When the pylorus is thrown into a state of spasm and closure—a condition termed pylorospasm—an enforced retention of the irritative acid chyme, combined with the prevention of ingress of the protective bile, tends to increase gastric irritation. It is obvious that the cardinal symptom of pylorospasm, one may well say its *sine qua non,* is the retention of food within the stomach seven hours after a meal.

The etiology of pylorospasm is not solely functional, as might perhaps be gleaned at first impression, but may be also organic. Spastic disturbance is evoked by such disorders as hyperchlorhydria of the vagal type, or again, by ulcer or adhesions to adjacent viscera.

Sippy declares that pylorospasm is largely due to hyperchlorhydria, and quotes by way of proof, that by proper neutralization of the gastric juice pylorospasm and pyloric stenosis were relieved in about eighty-five per cent. of the cases of ulcer. Pyloric stenosis diagnostically differs from pylorospasm in that the evacuation of water is usually protracted in the first condition and normal in the other. Elsner (10) emphasizes the observation that "intermittent hyperchlorhydria without ulcer may cause pyloric spasm and temporary obstruction."

Wayne Babcock (11) explains the gastric symptoms associated with pylorospasm so often noted in disease of the appendix, by the ileopyloric reflex, which, by guarding against overdistention of the small intestine just as the block system of our railroads prevents dangerous traffic congestion, maintains pyloric closure until the distended block below, ending with the ileum, has emptied through the ileocecal valve.

Radiographically, pylorospasm is manifested by a sharply cut off pylorus, total or partial retention of the motor meal, a deep cutting peristalsis of the 6-8 cycle type with its activity confined to the pyloric region, a transient hour glass contraction and finally, occasional deep incisura at the pylorus. This last manifestation must not be confused with the normal incisura at the pars pylorica and pars cardica, which, of course, are not spastic manifestations.

Because pylorospasm brings its sensation of pain in the right lower quadrant, the pain centre of so many other ills, it is a dangerous diagnostic sign. Heyd says "The pyloric syndrome of chronic appendicitis are symptoms due to pylorospasm associated with hyperacidity and hypersecretion of the stomach." Moynihan reminds us that the most frequent site for the production of the symptoms of ulcer of the stomach is the right lower quadrant. Yet withal, we estimate that the sign complexes made up of indirect manifestations are of great value. And, beyond doubt, a thorough analysis of the spastic phenomena in many cases of locomotor ataxia would preclude the possibilities of such mistaken diagnosis as abdominal condition, and prevent unnecessary surgical intervention.

I cannot let this opportunity go by without at least a passing reference to the law of average localization. I believe that this socalled law is of doubtful aid in diagnosis and that its use should therefore be circumspect. It is based upon an assumption that as the brain is possessed of a proper sense of direction, it therefore learns to localize sensations in the organism in which they arise. This law does not well apply to tabes, with its seat of trouble in the spinal cord, yet expressing its existence through gastric crises occurring irregularly, with intervening periods of health. Thus, with a periodicity such as is observed in gastric ulcer, with intense pain, vomiting, sitophobia—we have an ulcus syndrome staring in the examiner's face. Is it surprising that with such a clinical picture, the first impression should be not of a lesion remote from the primæ viæ, but of a gastric malady, most commonly an ulcus? And if the physician attach diagnostic value to the socalled law and be guided by his patient, is it not likely to lead even to surgical intervention? The patient is endowed with a gastroenterostomy—insult is added to injury. Rather, how much better it is to include in the routine examination, a search for neurological signs such as are furnished by a Romberg sign, diminished or absent knee jerk, or an Argyll Robertson pupil, also a serological study for Wassermann reaction, or reactions, for often one does not suffice! One recalls with pain a peritoneal incision for the abdominal reflex in lobar pneumonia; or a recommendation of a gastroenterostomy for a tuberculous disease, or syphilitic gastric ulcer!

Many writers regard the first portion of the duodenum—the duodenal cap—as a mere continuation of the pylorus, because of the smooth and unbroken continuity of outline of mucous membrane, and the absence of any valvulæ conniventes, the socalled winking valves of the small intestine. However, for the purpose of this article I shall maintain the distinction.

Cases of spastic duodenal irritation, apart from those with an organic background, are reflex in their origin. They may be brought about by a diseased appendix, incomplete ileocecal valve, mucous colic and gallbladder pathology. The shadowgraph picture will be that of hypermotility, hypersecretion, pyloric insufficiency, spasm (contracture of the greater curvature), a possible residue in the bulbus duodeni and in the pylorus. Carmen stresses the combination of hyperperistalsis, with gastric retention and a normal gastric outline, as diagnostic of duodenal ulcer with stenosis.

As regards enterospasm and its relation to digestive upsets, it is well to recall that the digestive functions are influenced by the coordination of the vagus and sympathetic nervous impulses and of those of the central nervous system, through an intermingling of fibres from the medulla with the sympathetic and ganglionic cells situated in the muscles and glands of the primæ viæ. Therefore a proper functioning is dependent upon maintenance of equilibrium between the two forces, very much in the manner that a normal temperature is maintained by the proper balancing of the forces of the thermotoxic centres, namely: those of the thermogenic and those of the thermoinhibitory and thermolytic centres. When, however, there is an excess stimulation of one of the forces, there is brought about a condition of vagotonia, similar to that previously explained in our discussion of the upper portion of the digestive tube.

The important intestinal affections of the vagotonic group are enterospasm, spastic constipation and spasm of the anal sphincter (6). The affections of the sympatheticotonic group are of a reverse nature: diminished secretion, atonic constipation, relaxed anal sphincter. Enterospasm and spasm of the anal sphincter are prolific causes of spastic constipation. Hertz asserts that chronic appendicitis is one of the most common causes of enterospasm.

Peristaltic unrest or visible peristalsis is usually diagnostic of intestinal or pyloric obstruction. The phenomenon first described by Kussmaul occurs in nervous patients under emotional stress, and is more readily observable when the abdominal walls are thin. Taylor and Miller, referring to this telltale phenomenon, state that it requires close and patient observation, as it is quite easily overlooked.

CONCLUSIONS.

We have found that certain spastic phenomena are normally present in the primæ viæ and that pathological conditions may arise which convert such physiological spastic demeanor into a state of abnormal activity.

We have found that certain phases of pathology betray their presence by evoking spastic activity. It is therefore patent that the abnormal spasm has value as diagnostic of the pathological state. It is an irregularity that sets us on inquiry, a sign post, which when read aright, indicates the therapeutic road. And in as much as these spastic phenomena owe their manifestations to some form of nerve excitation, due regard must be had for the personal equation—the nervous status—of the patient when seeking to establish the pathological basis.

It is well to remember that these spastic phenomena have a sort of inherent capacity for deception, as when they disappear in deep narcosis. It is therefore best to refuse to accept a negative x ray finding as a conclusion, unless fortified by clinical history and laboratory findings. "Absence of proof," says Koch, speaking of tuberculosis, "is no proof of absence." One must also beware of the pitfalls of socalled clinical mimicry.

There are divers maladies both within and without the gastroenteric tract which evoke it into spasm. This suggests that the search for the etiological factors must extend to all likely regions, not omitting the endocrines. It is confirmatory of the seemingly paradoxical maxim that the field of the specialist does not lie entirely within the confines of his specialty; that as a gastroenterologist he cannot view a case with a tubular vision narrowed to the limits of his special field of activity, and studiedly disregard conditions that do not happen to lie within it.

Finally, it is well to remember that in organs related anatomically, the manifestation of spasm in a viscus may be reflex, and that the true offender is elsewhere. Where surgical intervention is indicated, this reminder is doubly necessary. Let us bear in mind that exhaustive preoperative study minimizes postoperative digestive invalids, and such diagnoses as anxiety neuroses and postoperative adhesions.

The author's references will appear in his reprints.

Once a Cæsarean Always a Cæsarean?

By J. THOMPSON SCHELL, M.D.,
Philadelphia, Pa.,
Surgeon in Chief, Northwestern General Hospital.

This brief report is presented to express disapproval of the dictum stated in the title. There seems to be a popular belief that if a patient is once subjected to a Cæsarean operation it must necessarily follow that her subsequent deliveries must also be by the Cæsarean route.

My experience embraces 167 Cæsarean operations for various indications and I desire to report two cases in which each patient has had three normal deliveries since operation, two cases with two normal deliveries, and nine cases in which each patient has been delivered of one child each, all of these cases being spontaneous births.

In addition to this, my records show fourteen other cases in which delivery was by the vaginal route with the assistance of forceps, and one case by podalic version, making in all thirty-four babies that have been delivered by the vaginal route in women who have previously been subjected to Cæsarean section.

A number of the 167 women who were sectioned have been rendered sterile at the time of operation, at their request, although I wish to put myself on record as being opposed to this method as a routine procedure. Inasmuch as many of these patients were operated upon as referred cases, it is impossible to estimate how many other vaginal deliveries could be added to these already reported.

It is interesting to note, also, that there is no record of any case that has been followed by a rupture of the uterus. All of these operations have been of the conservative type with a small abdominal incision and a careful suturing of the uterus, with a total mortality in the 167 cases of two deaths. The patients have been operated upon without selection. The method of operation has never varied and many of them have been operated upon after forcep application has been first tried. In many of these cases there has been morbidity and a stormy convalescence but no deaths.

The two deaths reported were due, in one instance, to a placenta prævia infection, followed by general peritonitis and death; the second, to a cauliflower carcinoma involving and including the entire vaginal fundus. This patient became infected and died ten days after operation. One of this group was delivered by the Cæsarean route five times, one four times, two three times, four twice.

It is my opinion that Cæsarean operation of the conservative type is of small operative risk, that its usefulness will be more appreciated as time goes on, and that as a competitor for the high forcep delivery, it will, in the future, probably supersede the operation of forceps where the head is at the brim after the honest and prolonged test of labor has been made. In other words, a woman in labor for a prolonged period, say twenty-four hours, with the head still high up and presenting at the superior strait, but not engaged, it is my opinion that the conservative Cæsarean section is by far a better and safer operative procedure than the axis traction forcep delivery with its associated dangers to both mother and child.

Historical Medicine

An Appreciation of the Work of Johannes Walæus

A Pioneer of Vivisection

By G. ARBOUR STEPHENS, M. D.,
Swansea, England.

Johannes Walæus was professor of medicine at the University of Leyden about the middle of the seventeenth century. This celebrated old Dutch university was founded in 1575 by William of Orange and among those who were students in the days gone by we find the names of well known men, such as Goldsmith, Boswell, Evelyn, attracted thither by the reputation of its learned professors. To be elected to a staff that included such great names as Descartes, Grotius, Arminius, is indeed a high honor, and, although the name of Walæus is not well known, I venture to think that the following reference to his work cannot but tend to raise him towards the niche he so justly deserves.

At the end of a book, a translation of Bartholini's *Anatomy,* published in 1665 by Nicholas Culpeper, Gent. and Abdiah Cole, Doctor of Physick, it was my good fortune to come across

THE EPISTLES
of
JOHANNES WALÆUS
concerning the
MOTION OF THE
CHYLE
and the
BLOOD.
To Thomas Bartholinus
the son of
Caspar Bartholinus

Walæus gives us the reason for writing these epistles in his concluding remarks, as follows: "And thus (most worthy Friend Bartholine) I conceive I have answered your Question touching the motion of the Blood. Whereupon I did enquire more scupulously, that I might better know the Nature of the Humours, and their Deflux: from which Flux of Humours innumerable Diseases arise.

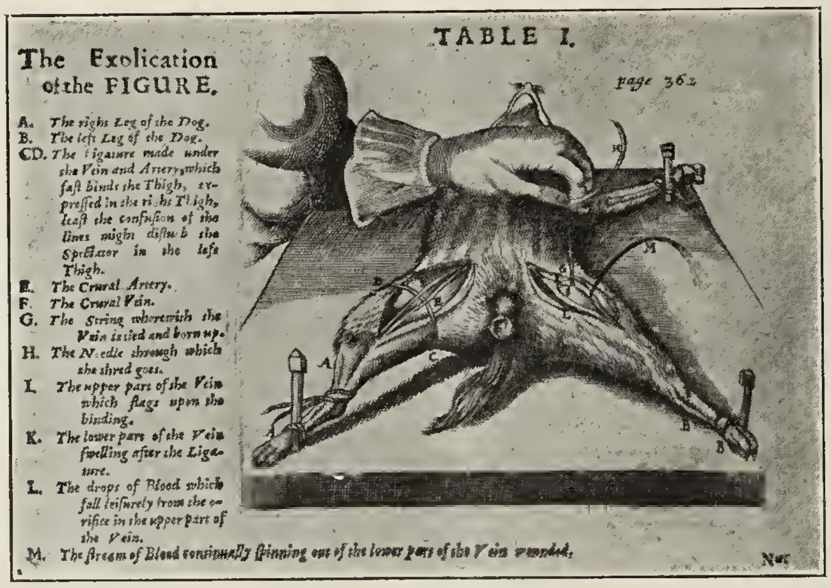

TABLE I.

page 362

The Exolication of the FIGURE.

A. The right Leg of the Dog.
B. The left Leg of the Dog.
CD. The ligature made under the Vein and Artery, which faſt binds the Thigh, expreſſed in the right Thigh, leaſt the confuſion of the lines might diſturb the Spectator in the left Thigh.
E. The Crural Artery.
F. The Crural Vein.
G. The String wherewith the Vein is tied and born up.
H. The Needle through which the thred goes.
I. The upper part of the Vein which flags upon the binding.
K. The lower part of the Vein ſwelling after the Ligature.
L. The drops of Blood which fall leiſurely from the orifice in the upper part of the Vein.
M. The ſtream of Blood continually ſpinning out of the lower part of the Vein wounded.

Fig. 1.—Vivisection experiments on the dog demonstrating circulation of the blood.

"And the Experiments wherby I was brought unto this Opinion are so evident that I doubt not to affirm, that learned and discreet Physitians will henceforward allow of this Motion of the Chyle and of the Blood.

"Touching the truth of these Experiments you cannot (my Bartholine) make Question who have yourself seen many of them: and there were frequently present most learned Doctors of Physick and persons of solid Learning.

"And so farewell, most learned Bartholine, and persist to love me.

"Dated at Leyden, the 10 of the Kalends of October, Anno 1640."

Thus ended the first epistle, while at the end of the second we find these words: "These are the things (most excellent Bartholine) which I thought fit to joyn to the former, that I might satisfie those who cannot receive a new opinion, wherein they observe any difficulty or obscurity; who many times have neither minds nor time to enquire exactly into the bowels thereof. But in my judgement, we ought not to deny things manifest, although we cannot resolve such as are difficult."

"But I never was disposed to contend and quarrel with any man about words. There are very many excellent things about which time may be spent, which many times is not sufficient for our necessary occasions. Also from a Scoffer that seeks after her knowledge does hide herself away, but to him that is studious of the truth, she comes to meet and presents herself to his views. Farewell, most learned Bartholine. From the University of Leyden in Holland, the Kalends of December 1640."

It should be pointed out that these experiments were performed soon after the great Harvey had published his new and revolutionary theory, and at a time when opinions were disturbed to a tremendous extent throughout the medical world. Hot words were being handed about, and recriminations indulged in to make things very unpleasant, so that the delightfully charming manner in which Walæus writes to his beloved friend Bartholine at Copenhagen is all the more remarkable.

These epistles are written apparently after many pressing requests, for he says: "Howbeit you continue your Requests and I am much ashamed alwaies to deny you." His hesitation to reply is due, as he points out, to the fact that "No man can publish in Print which some account excellent, but he presently meets with a Detractor who will cut and tear him most cruelly. Now, for a man to seek nothing else by his Cares and labours, but Envie and Vexation of Mind is extreme madness."

Having at last pulled himself together he sets out in right earnest to give Bartholine a full and clear account of the motion of the blood, supported by his own personal experiments on the living animal. He first of all puts the question, "What blood it is which is moved?" and answers it by saying, "When we have taken Blood out of the greater Arteries, and from the same Creature have taken some out of the

Veins, and have let them both grow cold and congeal, we could never observe any difference betwixt them. So that we can see no other but that the Arterial Blood is of the same kind as the Venal." The conclusion he arrives at is that there is need to inquire into the motion of only one sort of blood. This motion, he points out, is not a to and fro motion or "an up and down motion in the Vessels like boyled water" as some of his contemporaries suggest, but "that the Blood is moved from one part of an Artery or Vein into another is a thing very manifest. For Blood is contained in the Veins of the furthest parts of the Body, which seeing it is not bred there, it must needs come from some other place."

Walæus is nothing if not thorough, for he points out that in order to understand thoroughly the whole motion of the Blood, "our best way will be to begin at the very Fountain and Original thereof." To do this he starts with the Chyle and shows that the meat eaten is closely embraced by the Stomach and "moistened with the moisture of the Stomach." "It is cut and minced by an acid humour . . . which comes from the Spleen."

After the food has been properly digested it is converted into Chyle, where he says it is "of an ash color, and presently from the Duodenum it begins to enter the milkie veins of Asellius." In order to prove that the milky juice does not get into the lacteals from anywhere else than the gut, he performs a vivisection experiment as follows: "I have bound these milkie veins inserted into the body of the Guts, and observed that from the cavity of the Guts to the ligature they are evidently full and swoln, but from the ligature to the Mesentery they wax empty and fall in." The chyme, he tells us, "is mixed with the Blood in the Ramus mesentericus, in the Vena portæ and in the very liver also itself." Although he knows that the ultimate branches of the vena porta do not join up to those of the vena cava, yet he is quite convinced that blood mixed with chyle does transfuse, and then passes out of these latter into the vena cava itself, for "When in live anatomies it is tied above the liver, it manifestly swells with Blood flowing in."

He then tells us that the blood passes out of the vena cava into the heart, and out of the right ventricle of the heart into the "Vena arteriosa, but not through the septum of the Heart," "for I find no open passages in this place; although Gossendus had seen Payanus shew the Partition of the Heart to be transpassable by sundry crooked and turning passages . . . and the truth is I have divers times found it to succeed as he saies; but I have withall observed that those waies and turning passages were not all made by Nature, but by the Probe or point of a Penknife."

It is very difficult to believe that there were physicians who could stoop to such deception in connecion with an investigation connected with the heart, upon which investigation treatment would eventually have to be based. Such characters, however, were n evidence in those days, for Walæus tells us that "learned men have in no Age more ambitiously striven who should seem most learned than at the present time. And to attain their very desire very many are not afraid to assist themselves by Calumnies and other worse Arts."

He gives details as to how the blood passes into the lungs, thence to the left side of the heart, the aorta, and the rest of the small arteries. The capillaries he does not seem to know as such, for he had no microscope, but he tells us that "the blood out of the small Arteries may enter into the Veins, for the Arteries have a way open into the veins by the common mouths of one opened into another." He emphasizes his point by quoting Galen to the effect that, if a large artery be opened, one may draw all the blood in its body out through the said arteries, but to make it quite conclusive Walæus performs one of his innumerable vivisection experiments.

The accompanying diagram gives us an excellent idea of the way in which he carried out the operation to show "that the Blood did not come downwards from the greater Vessels but upwards, out of the smaller Vessels into the greater."

After having demonstrated the completion of the circulatory circuit via the large veins into the vena cava and back to the heart he raises the question, "how much comes from the Heart at every pulse" and proceeds to tell us that we cannot determine it exactly, but "this I can witness, that out of the Heart of a Rabbit there hath come at every pulse half a dram of blood, and out of the Heart of a great Water spaniel half an ounce; yet I conceive more comes out when a live Creature is Dissected than when it is in Health. And if a man would determine by conjecture from what we have seen how much may come out of the Heart of a Man in health at every pulse, I shall not be against those who say half an ounce of Blood is shed into the Arteria aorta." This estimate compares favorably with our most modern one, but whereas his was done soon after Harvey's discovery, ours had all the advantages of careful thought about the subject.

To Walæus it is a matter of great surprise that this circular motion of the blood was not discovered before Harvey made his appearance, for he tells us, "Truly I cannot sufficiently wonder, that in so many Ages past, this motion of the Blood hath been unknown, seeing I find sundry and those no small intimations thereof in the ancient Writers." He points out that Hippocrates in his book *de Victus ratione* attributes these circular motions to our "Heat and Humours whereby they are moved inwards and outwards." In another book of Hippocrates, *de Os . . . Natura,* we are told that, "The Veins being spread through the Body, do cause a fluxion and motion, sending many branches from one. For it keeps in a circular course so that you can find no beginning." Another author from whom he quotes is Diogones Appolloniata, wherein he finds "The most thick Blood is suckt by the fleshy parts and that which redounds into the greater Veins becomes thin, hot and froathy." Plato and Aristotle are also brought in to show how near the ancients were to a sound solution of the problem, the latter stating "that the Heat of every Animal when it comes aloft, it soon after circulates and descends again."

After these ancient writers there seems to have been no work done in connection with the subject, even Galen for whom he apologizes, "not being able to reform all things, and the latter Greeks, Arabians and Latins have too close followed him," evidently being content with accepting things from those in authority rather than adopting methods similar to those of St. Paul of proving all things, or of praying for all those in authority! Is there not too great a tendency these days to rely on authority rather than to think things out for oneself? Far better it seems to me to come under the castigating hand of Walæus for trying to support a false theory by worse experiment than to accept anything or everything that is offered to us. The great aim of vivisection is to make each man think for himself, and any socalled medical education which tends to make medical men diagnose by rule of thumb deserves to be censured most severely.

It was by observation that Paulus Servita, the Venetian, discovered the structure and use of the values in the veins, and as Walæus tells us, "The most learned William Harvey, being taught by the aforesaid Paulus Servita, did more accurately search into this motion of the Blood, augmented the same with inventions of his own, proved it strongly and published it to the world in his own name. Such," he adds, "hath been the invention and such the fate of this motion of the Blood." Walæus raises the question as to "how soon the Blood performs the Circuit from the Heart to the Heart again" and has to admit the difficulty of determining this precisely, but says, "We observe that it is done sooner by an Anastomosis nearer the Heart, than by one off." He adds, "Howbeit, it goeth not so swiftly as we see it leap out when a Vein or an Artery is opened, because then it is moved into the free and open Air: but within the Body it is compressed to lift up the Vessels, and to thrust on the foregoing blood."

In connection with the subject of fevers Walæus tries to explain why they are not always "alike fierce" and comes very near to the modern explanation of malarial fever when he says "because it doth not cause a Paroxism till it have attained a certain degree of putrefaction; and that the Fit lasts so long till that putrid matter be evacuated." Had he but had a good microscope, what discoveries he would have made! "But," he tells us, "it is now time to enquire into the Causes of these motions" and proceeds to point out "either it must be moved by an inbred virtue or faculty, or by some motion which must be referred to carrying, drawing, or thrusting." That it does not move of itself he proves by pointing to the fact that blood drawn into a basin shows no spontaneous movements whatever. Nor will he admit that it is moved by the spirits, for "they by their lightness should move the blood upwards, which we see here to be moved downwards and sidewaies."

Some had put forward the argument that the blood is driven from the heart by a certain heat causing rarefaction of the blood which then "requires greater space and therefore dilates and lifts up the Heart." This explanation was not a foolish theory but had for its support the fact that the heart of an eel when it ceases to pulse, if it be warmed, starts to pulse again. Walæus admits this experiment but shows that "when the Guts and Muscles are heated in a live Dissection, in which there is no ebullition, the motion seems to be restored," and realizes that heat is only a mere stimulant. There are other stimulants to the heart muscle of which he is aware, such as "a prick with a Penknife or a Pin," and Walæus considers that a change in the constitution of the blood acts as a stimulant also, and here he is quite right.

We now come to a point that is of very great interest to us these days when so much is said of sinoauricular nodes, fibrillation, flutter and heart block, for Walæus, according to this epistle, seems to have anticipated all these things. He tells us "that the Blood is driven by the Vena Cava into the right Earlet of the Heart, I have manifestly seen in the dissection of live creatures; for in all motion of the Heart, the first beginning of Motion is so or no, because the Cava was knit to the Earlet and the Heart. We cut the heart and the earlet quite off in living dogs at the Vena Cava and we observed that even then the Vena Cava did a little pulse and at every time did send forth a little Blood. And therefore the Vena Cava hath certain fleshy fibres for the most part near the heart, which elsewhere you shall not find in the Vena Cava. Now the motion of the Vena Cava is most evident near the Heart."

Compare the above which was written in 1640 with the following quotation from Lewis's *Clinical Disorders of the Heart Beat,* written in 1913:

"The complete beat of the normal heart consists of a contraction of its chambers in an orderly sequence. The wave of contraction starts in a small and newly discovered (sic) mass of tissue, the sinoauricular node which lies embedded in the upper and anterior end of the sulcus terminalis running from the junction of the right auricular appendix and the superior vena cava towards the inferior vena cava."

Sir James Mackenzie gives the credit for this discovery to Keith and Flack, being evidently quite oblivious of the work done by Walæus.

Walæus tells us that "in the Earlet the motion or constriction is a little sooner than it is the Heart but the impulse into both Earlets and into both the Ventricles happens at one and the same moment of time: Save in creatures ready to die in which we have observed that both Earlets and both Ventricles do not pulse at one and the same time."

In a paragraph on personal experiences, Sir James Mackenzie claims that "my attention was first directed to the condition of auricular fibrillation as a separate and definite entity about 1890," and proceeds to give Lewis's definition of that condition as follows: "The walls of the auricle stand in the diastolic position: systole, either partial or complete, is never accomplished; the wall as a whole is stationary, but careful examination of the muscle reveals an extremely active condition. It appears to be alive with movement; rapid, minute and constant twitchings or undulatory movements are observed in a multitude of small areas upon its surface."

Let us hear what Walæus had to say in 1640 on the same subject. "But when the Blood is thus driven into the Ventricles of the Heart, the Heart hath no motion evident to the Eye, but putting our Finger upon the Heart, we perceive somewhat to enter into the heart and that the Heart becomes fuller which also Harvey hath observed in his fourth chapter. Yea we have observed that the Earlet hath pulsed seventy, sometimes an hundred pulses before any motion of the Heart followed."

One cannot refrain from exclaiming as did the preacher a few thousand years ago: "that there is nothing new under the sun."

If Walæus had been in a position to use electricity as a stimulus in some of his experiments, his contributions to medical science would have been still greater, for even without it his work is quite up to date in its suggestiveness. Take for example the following paragraph: "In the Particles of a live heart dissected and taken out of the Bodie, where constriction has ceased, there remains a seeing kind of Palpitation but that is another kind of motion proceeding from the spirit contained in the flesh and seeking its way out; such as may also frequently be seen in the muscles whole or dissected in Creatures dissected presently upon their death."

It were well for some modern experimenters to note the above and realize that all motion of the heart muscle is not the same motion.

Walæus must have been a hard and diligent worker, for the number of experiments he seems to have performed on living animals of various kinds is enormous.

Among those he mentions in the course of these epistles are dogs, rabbits, cats, monkeys, while he dissected large animals including one whale in order to satisfy himself as to the anatomy of the heart and to show that Aristotle's statement in *de partibus* that "the greater sort of Animals have three ventricles in their Heart. For the greatest Animals that are have but two Ventricles as I observed in the Dissection of a young Whale."

Had he but known the value of asepsis, the surgery of the heart would have been a matter of ancient history by now, for the numerous experiments he performed successfully in connection with that organ and its big vessels are worthy of being considered as masterpieces.

As a vivisector he must be considered a prominent pioneer though he himself gives credit to Galen for having done some experimental work on living animals in connection with the arteries.

When treating of the veins, Walæus makes one interesting suggestion which if true must be considered as of great importance. He says "In the Vena Cava, there is a certain Storehouse of Blood wherein blood is treasured up for future uses, when it is more plentiful then that all of it need be sent into the Heart."

As Walæus wrote to Bartholine "also from a Scoffer that seeks after her knowledge does hide herself away, but to him that is studious of the truth she comes to meet and presents herself to his view," so it might almost be said that Solomon wrote in anticipation of Walæus. "I wisdom I dwell with prudence and find out knowledge of witty inventions."

Leonardo da Vinci as a Scientist.—Dr. John C. Hemmeter (*Annals of Medical History,* March, 1921) gives us, in this full and very interesting article, in addition to other data on the life and work of da Vinci, an outline of the history of anatomy up to the time of the great man. He tells us that the status of anatomy in the Middle Ages was deplorable. The medieval doctor owed his scant scientific knowledge to the Arabs, and they were forbidden by their religion to open cadavers. In the Occident also the opening of cadavers was also for long periods forbidden, but not altogether, during the Middle Ages. "Mondino de' Luzzi of Bologna (1326), whose book on anatomy, copied in part literally from the canon of Avicenna, an Arabic physician (980-1036), was in almost exclusive use in all the medical schools of Italy for more than two hundred years, mentions as something quite remarkable that he had dissected three cadavers."

So Leonardo was entirely without sources for the study and representation of the human form, but he resolved to acquire information. He found a congenial spirit in these researches in Marco Antonio della Torre, the founder of a medical school at Pisa, who was willing to apprentice himself to nature and dissect cadavers. From these Leonardo made a series of magnificent anatomical drawings, which remain as a perpetual monument to these two originators of illustrative anatomy. The original file of these was lost until the eighteenth century, when it was discovered by Dalton, librarian of George III, in a closet in Kensington Palace together with some sketches by Holbein. The volume contains 779 drawings, incuding illustrations in optics, and of bones, muscles, bloodvessels, viscera, brain, eye, ear, and other organs and portions of the human body, all executed with the utmost fidelity to nature. These drawings, it is stated, surpass in some respects the famous illustrations in Vesalius's anatomy, so long ascribed to Titian. J. Hunter, the most eminent anatomist and physiologist of the eighteenth century, declared that da Vinci was the best anatomist and physiologist of his time; Knox, a famous English anatomist, stated that his drawings of the valves of the heart, and especially of the semilunar valves of the aorta and of their varying positions, could be founded only on a correct conception of their functions. Hence it has been assumed that Leonardo may have known of the circulation of the blood a hundred years before Harvey.

The great artist did not content himself with a knowledge of the defunct body, but extended his investigations to include the physiologic functions of several of the organs. The results of these researches are recorded in part in his treatise on painting, in which he discusses the relative conditions of the body at rest and also of its movements, both voluntary and involuntary. "He begins with the flexions and extensions of the several members, and explains walking quite in the sense of modern physiology, as a constant falling forwards. Then he expatiates on the influence of occupations on the carriage of man in explaining which muscles are active in lifting, in carrying, in supporting a load, in raising an arm for throwing or for swinging a club, and how the body remains in equilibrium in the positions variously conditioned by these muscular activities. Leonardo might well have been the first to institute investigations on the statics and mechanics of the human body. . . . To grasp correctly the involuntary movements, such as are expressive of pain, of joy, of fright and of other emotions, he advises the young artist to mingle with the common people, among whom the emotions are revealed unrestrained in the facial expression and in the gesture."

INDUSTRIAL HYGIENE

In humorous vein a writer in *Scribner's* Point of View insists that man is having health thrust upon him at such a rate that he will soon be bereft of all the pleasures of invalidism and robbed of those finer qualities of character which Hamerton and others have pointed out as begot only of ill health and unknown to the always rugged and robust. Man, in the more primitive state, however, is very resistant to that which goes against custom and personal habit, and it is not likely that the need for hospitals and medical men will be dispensed with at once. Students of industrial hygiene find their subjects especially uninterested in health or in securing such conditions as make health in their industry possible. They are vastly more interested in trying to get a small increase in wages than in having improved conditions in factory or mine.

During the recent anthracite strike a number of open letters appeared in the daily papers affirming and denying that coal mining was an unhealthy occupation. A physician engaged in industrial work recently interviewed a president of one of the local unions in the anthracite district, and was told that "there isn't any more miner's asthma than among other people. There's just as much miner's asthma among women as among men." Another president of a local union said, "Miners are as healthy as other people. Why, there isn't more than ten per cent. of them has asthma." It was suggested that ten per cent. was a large proportion, but the suggestion made little impression.

So far as this industry is concerned it has long been remarked that deaths from tuberculosis (according to the death certificates) are few as compared with the population at large, about five per cent. as compared with twenty-five per cent. for all occupied males. Even making allowance for the high death rate from accidents, the rate for tuberculosis still remains significantly low. However, the amount of sickness, disability, and death from other respiratory diseases probably vastly more than makes up for the relative freedom from tuberculosis, and, while anthracosis and miner's asthma may not be so frequent or in such aggravated form as when mines were less well ventilated, there is still much that needs to be done in the way of preventive measures against these dust and fume diseases. The whole subject has been much neglected and a study of the matter has recently been taken up by the Public Health Service. They will meet with difficulties in their endeavors to get at the facts of the matter, but we shall look forward with great interest to the outcome of their investigations.

THE USE OF INSULIN BY THE GENERAL PRACTITIONER

It may be stated quite definitely that the use of insulin for controlling diabetes is a conspicuous success. It has its distinct limitations; that is, it is not a cure, but these limitations are fairly well known and, considered from most aspects, the production of insulin is an epoch making event and one which, moreover, seems to point the way to other discoveries of a more or less similar nature. The therapeutic value of insulin is so great and the prevalence of diabetes is so wide that the remedy should be within the reach of all classes of society. Unfortunately the cost is a very considerable obstacle to its general employment. On the other hand, the condition occurs most frequently among the prosperous and well fed—it is held by some to be a disease mainly due to overeating—who can afford to pay for the treatment.

The next points are that an accurate diagnosis shall be made and that the treatment shall be carried out scientifically. Of course cases of diabetes come mostly within the province of the general practitioner and he has to teach himself how to diagnose correctly, at any rate, or the consequences in some cases may be disastrous.

At a meeting of the Section of Therapeutics and Pharmacology held in the house of the Royal Society of Medicine, London, on October 9th last, the use of insulin in general practice was discussed. Professor Hugh Maclean, in opening the discussion, said that the nonsuccessful cases were probably those unsuitable for treatment. If the doctor followed the directions carefully insulin could be safely used by him. The most important point was to go slowly. But every care must be taken in the matter of diagnosis. Insulin given in too large doses produced certain symptoms, such as flushing of the face, followed by pallor; and there might be local or general sweating, and a sense of constriction about the chest, or a feeling of impending disaster. Even unconsciousness, or motor or sensory aphasia might result. Professor Maclean pointed out that insulin, in nearly every case, gave the patient a sense of comparative well being and he was more energetic. In an unsuitable case the danger of giving insulin was very great. He did not think one could forecast, in a given case, what would happen in four or five years; but when eye changes occurred, there could be little hope of doing the patient good, though an effort could be made to eliminate the blood sugar by giving insulin. He had not yet seen a bad case of diabetes cured by insulin. In cases in which sugar appeared in the urine because of a leak in the kidney the giving of insulin might bring about disaster. If one went slow with the remedy, and the patient was meanwhile carefully watched, it was impossible for the general practitioner to go far wrong. A definite diet should be decided upon, and that should be adhered to practically throughout the treatment.

The insulin should be commenced with a small dose, and the quantity very gradually increased. He did not think it was necessary that those using insulin in general practice should be able to test the blood sugar. In every case the aim should be to render the urine sugar free. Even in cases where this was not achieved, the patients said they felt much better, and seemed to have more energy than normally. Another speaker, Dr. George Graham, said that while he had no doubt that insulin was of very great value in the treatment of diabetes, it could not be considered a substitute for the diabetic treatment. The more knowledge a doctor had about the disease, the better were his results likely to be. The ideal to be aimed at in the treatment was to render the blood sugar normal. In a case of coma, one got the answer as to the value of insulin treatment in four or five hours, but in mild cases one might have to wait years. Professor J. J. R. Macleod, of Toronto, stated that in Ontario, classes of instruction, two or three days each, had been largely attended by practitioners to learn about insulin, the various tests, and the behavior of the patients, and the Ontario Government, through the Provincial Board, were supplying to the profession insulin free of charge for use for poor patients. Dr. Poulton considered the use of insulin by the general practitioner was safe provided he proceeded slowly.

It appears, then, that the use of insulin by the general practitioner is safe, provided he exercises great discretion. But he must become scientifically versed in its employment and above all must be able to diagnose with accuracy. As a matter of fact, in the existing circumstances it seems that the general practitioner as a rule, and the country practitioner in particular, is not competent to administer insulin with confidence and perhaps his diagnosis is not always to be relied on. The general practitioner, in many instances, requires to be instructed in diagnosis and more especially as to the scientific employment of the remedy. The example of Ontario in establishing classes of instruction for practitioners to learn about insulin, the tests and the behavior of the patients, is one which might be followed in this country with benefit to all concerned, as well as the example of the Ontario Government in supplying to the profession insulin free of charge for the use of poor patients.

In many other respects the Ontario Government is setting a good example to the civilized world by the manner in which it is fighting against disease and caring for the health of its people. Recently it gave an object lesson in this direction, by voting to Dr. Banting an income of seven thousand five hundred dollars a year in order that he might continue to pursue medical research. Moreover, that he might be able to do this with a mind free from financial worry. Up to the present time research has been hindered and hampered by pecuniary considerations and in consequence progress has been comparatively slow. It is to be hoped that a new era is opening. As said before the discovery of insulin marks a new departure and holds out high hopes for the future. So far as the general practitioner and insulin are concerned, it may be said that generally speaking he requires more scientific instruction in its use from several aspects, but that with time and experience insulin will be in common employment among general practitioners. In the meantime the product itself will be improved and more learned of the matter in every way. The beginning of this form for treating diabetes is most promising.

WHOOPING COUGH

Each season brings its new contribution to the cure or alleviation of whooping cough. Of late, also, the discovery of the cause of the disease is a perennial announcement. The past year has given us two new methods of treatment. The intramuscular injection of ether is or was said to be effective. Surely this ought to have some effect, for a child that received such treatment would try mightily to suppress a cough that would bring on another injection. If this is a helpful remedy it certainly works along psychological lines.

The latest successful treatment of the disease to be announced is exposure to x rays. It was logical that the rays should be turned upon this disease sooner or later—logical, because it is being tried upon everything. It is said to produce wonderful results, again, probably, through mental processes. The machinery of the x ray production is impressive. We hope that both of these means of cure are as effective as they have been advertised, but in saying as much we are reminded of the colored preacher who expressed the hope that a deceased brother had gone "where we think he hasn't."

An outstanding feature of cures for whooping-cough is that they are effective with lapse of time, and the more time the more effective they are. Possibly, also, not a few of them, as we have dared to hint, have had some mental effect. Attempts have been made at quarantining the pertussis patient and with good reason, but the slow onset and difficulty in early diagnosis of the disease, together with its prolonged course, make isolation particularly difficult and unsatisfactory. The disease is usually in a communicable stage before it is recognized, the period of confinement of the child is a long one, and, besides, a great many cases are never reported. In some communities the tagging of the child has been tried instead of placarding the home. Certainly, in schools, the child with the cough should be excluded until the nature of the disease is determined. Even where reporting of cases and quarantine is incomplete it is well worth while, inasmuch as one group of the population, that which employs a family physician, is afforded some protection.

Besides entailing more prolonged suffering than any other disease of childhood, it is a most serious one from the high mortality in infants and its serious sequelæ which are probably more frequent than we know. It is to be hoped that the field of laboratory study in the prevention of this dread disease will not be neglected for the more spectacular affections of adult life.

WOMEN IN MEDICINE

Women have invaded the provinces of men in many directions and to some extent, it is difficult to indicate to how great an extent, have competed with them successfully on more or less equal terms. In this country and in Great Britain women have entered the medical profession in perhaps larger numbers than other professions, and on the whole appear to have justified their selection of a career. Opportunities in the medical profession are more frequent possibly in Great Britain for women in medicine than in America because preventive medicine seems to be making more progress in the former land and offers better facilities for women than ordinary practice. As a matter of fact, there are few women in general practice. Reviewing the matter from all angles, it may be said that although it is many years now since women were admitted to medicine their progress has lagged somewhat. They appear to be only adapted for certain forms of medical practice, evidence of this lack of adaptability was shown during the war more with women than men. Perhaps, physically and physiologically, they are not fitted for the rough and tumble of war or even of general practice and yet it is not wise to be dogmatic on this point as their powers of endurance are frequently greatly underestimated. In the factors which make for success in any sphere of life, it may be that women are not so well equipped by heredity as men.

Speaking a short time ago at the opening of the winter session of the Royal Free Hospital School of Medicine for Women in London, Sir Humphrey Rollesten, president of the Royal College of Physicians, pointed out that it had been recognized since Darwin's day that variability of body and mind was more frequent in men than in women, and this led to a greater proportion of genius, and its opposite, in the male sex. Men had a greater aptitude for the abstract, and women for the concrete. Taking as instances Lister, Osler and Horsley, he suggested that so far there had been no women's names of equal weight. The number who before or after qualifying gave up medicine was greater among women than men. Marriage depleted the ranks of medical women; the ablest fell by the way. Statistics showed that about thirty per cent. of women married before or after qualification. Genius was an extreme variation of Nature, and as there was greater uniformity among women, the number of geniuses was reduced. Women as a class, however, inherently were more lawabiding and conservative, through the long continuance of man's supremacy. Women were naturally intuitive, and in some cases it almost amounted to clairvoyance. This quality was of great importance in diagnosis and prognosis to the woman doctor when reinforced by training.

The speaker rightly insisted that much depended on mental and physical makeup, and women students should remember that as a class they were more likely to mental breakdown. It would appear that there is a definite place for women in medicine but that, at any rate, in existing circumstances they are not nearly so well fitted as men to practice medicine. In the course of time a type of woman may be evolved who will equal man as a practitioner of medicine, but that time has not come yet. Moreover, if it does come, she will lose some of her traditional womanly qualities, and will probably be of less service to the race than in former days.

Obituary.

E. F. BASHFORD, M. D., O. B. E.,

London, England.

Major Ernest Francis Bashford, M. D., O. B. E., late director of the British Imperial Research Fund and adviser in pathology to the British Army on the Rhine, passed away at Manderscheid, Germany, on August 23, 1923.

Dr. Bashford was known all over the world for his researches into the causation of cancer and was especially well known to the medical profession of America which he visited more than once. He was born in Cheshire, England, in 1873, and studied at the University of Edinburgh, Berlin and Frankfort. He took the degree of M. D. with gold medal in 1902 and in addition was Van Dunlop scholar in anatomy, chemistry, zoology and botany; Mackenzie Bursar in practical anatomy; Whitman prizeman in clinical medicine; Holdsworth Research Scholar in experimental pharmacology; Stark Scholar in clinical medicine and pathology; and Pattison Prizeman in clinical surgery. When he graduated he was awarded the McCosh graduate's scholarship for study and research in the medical schools of Europe, and went to Germany where he studied bacteriology and pharmacology at Berlin University and worked with Ehrlich at the Royal Prussian Institute for Experimental Therapeutics at Frankfurt. He also studied at Frankfurt as Weigert-Grocers Research Scholar from 1900 to 1902 and was awarded the Milner Fothergill Gold Medal in therapeutics at Edinburgh University in 1901. He became assistant to the director of the Pharmacological Institute, Berlin, in 1901, and assistant to the professor of materia medica, pharmacology and clinical medicine in Edinburgh in 1902.

As said before, Dr. Bashford made a great reputation in Great Britain and in Europe, as well as in this country, by his investigations into cancer and also in toxicological research. He founded the modern experimental investigation of cancer in Great Britain and placed the statistical and biological investigation of that disease upon a comparative basis. He was honorary president of the First International Cancer Congress at Heidelberg in 1906. In 1911 he was awarded the Walker Prize for the quinquennial period 1905-10, and during 1911 and 1912 he was Ingleby Lecturer at the University of Birmingham, Middleton Goldschmidt at New York, and Leyden Memorial Lecturer at Berlin.

PAUL WATERMAN, M. D.,

Hartford, Conn.

The New York Neurological Society, at its 406th regular meeting, held on October 2, 1923, adopted the following resolutions on the death of Dr. Paul Waterman, which occurred recently at his home in Hartford, Conn.:

Whereas, It has pleased God in His infinite wisdom to remove from us our fellow member, Paul Waterman, of Hartford, Connecticut; and

Whereas, The Society feels that in his death it has lost a friend distinguished alike in his chosen field of medicine, in the civic life of his city and State, and in the service of his country in the World War; be it

Resolved, That the members of the New York Neurological Society extend their most sincere sympathy to the family and friends of Colonel Waterman; and be it further

Resolved, That copies of these resolutions be sent to the family, to the *Journal of Nervous and Mental Disease*, the *Archives of Neurology and Psychiatry*, the New York Medical Journal and Medical Record, and a copy preserved in the archives of the Society.

Edwin G. Zabriskie, *President*
L. Pierce Clark,
Chas. E. Atwood, *Secretary*,
Committee from the Council.

News Items.

Dr. Gehrung Honored by French Government.—Dr. Julien A. Gehrung, of New York City, has been made a Chevalier of the Legion of Honor by the French Government. He served in the medical corps of the French army before the United States entered the war.

New Officers of Mental Hygiene Committee—Dr. William H. Welch, dean of the School of Hygiene and Public Health at Johns Hopkins University, Baltimore, was elected president of the National Committee for Mental Hygiene at its annual meeting at the Hotel Pennsylvania recently to succeed Dr. Walter B. James, of New York. Clifford W. Beers was reelected secretary and Otto T. Bannard, treasurer. Dr. Charles W. Eliot, president emeritus of Harvard University, and Dr. Bernard Sachs, of New York, were reelected vice-presidents.

New Dean of Johns Hopkins Medical School.—Dr. Lewis Hill Weed has been named by the trustees of Johns Hopkins University as dean of the Medical School. Dr. Weed, who is professor of anatomy at the institution, succeeds Dr. J. Whitridge Williams, who recently resigned to devote his time to the women's clinic of Johns Hopkins Hospital. He joined the Johns Hopkins faculty in the fall of 1914 as instructor of anatomy. Since 1919 he has been a full professor in anatomy. During the nine years he has spent at Hopkins Dr. Weed has been associated closely with Dr. J. Whitridge Williams.

Tuberculosis Campaign for Lower Manhattan.—More tuberculosis is prevalent south of Fulton Street, lower Manhattan, than in any other section of equal area in the entire city and the death rate is three and a half times the average for this disease. In the hope of effecting an improvement in this condition the Bowling Green Neighborhood Association has started a campaign for cooperative effort in fighting the disease in this locality. This district is exactly twenty-five years behind the times in tuberculosis death rate, its rate for the disease today corresponding with the average for the entire city a quarter of a century ago. For every tuberculosis death in the district there are six living cases. Medical experts estimate that one out of every sixty persons in the downtown area is afflicted with the malady.

Jersey Vital Statistics.—There were 2,793 deaths in New Jersey during the month ended September 30th, according to vital statistics of the State Department of Health. There were 426 deaths among children under one year of age; 142 deaths of children over one year and under five years of age, and 955 deaths of persons sixty years of age and more. There were 27 deaths from suicide, as compared with 35 during the previous month. Diseases of the circulatory system caused 460 deaths in September; nervous diseases took 307 lives. Cancer and other diseases considered incurable claimed 268 victims during the month. There were 222 deaths from Bright's disease, 164 from tuberculosis, 175 from diseases of the digestive system, and 163 deaths from infantile diarrhea.

(*From our own correspondent.*)

London, *October 26, 1923.*

PERIODICAL MEDICAL EXAMINATION.

It has been suggested that policy holders in insurance companies should be examined periodically, and this subject was discussed recently at a conference convened by the Federation of Medical and Allied Services presided over by Sir Malcolm Morris. Among those present were Sir Thomas Horder, chairman; Sir Squire Sprigge, editor of the *Lancet;* Dr. N. Howard Mummery, medical director of the Federation, and representatives of a large number of insurance companies. Sir Thomas Horder said that they wanted to extend the wise practice of seeking a periodical overhauling of the body, in order that signs of departure from normal health might be detected before disease manifested itself. The first step seemed to lie with the life insurance offices, which could encourage the practice by offering inducements to their policyholders to benefit themselves, decrease mortality, and improve the general health. He recommended, however, that the adoption of the proposal should be gradual, or they might alienate a large section of the community. Major L. G. S. Molloy, M. P., moved a resolution approving the principle. It would, no doubt, he said, tend to prevent disease. It would be a great advantage to the policyholders, provided it were gratuitous, and to the medical profession, who would conduct the examination, although it would involve a great deal of expense to the insurance companies. The discussion which followed the speeches disclosed the fact that the insurance companies were by no means convinced that the adoption of the principle would be to their advantage. Dr. Otto May moved an amendment expressing approval of the periodical medical examination "of all citizens" as being more noncommittal and this was substituted for the original resolution which restricted examination to policyholders.

MEDICAL MEN AND PROHIBITION.

At the present time a conference of the *Ligue Internationale des Adversairies des Prohibitions* is being held in London. At the opening session Sir Archdall Reid, who has written one of the most scientifically emphatic books on the subject of alcohol, and on alcoholism and heredity, was the principal speaker. The title of his paper was the fallacy of prohibition. He declared that he was strongly in favor of keeping the habitual drunkard sober by force if necessary and of forbidding him to perpetuate his kind. A law forbidding offspring to inebriates, said the speaker, would, like other laws, have its successes and failures. At any rate, prevention of offspring to them was the sole possible road to racial temperance. He pointed out that many races of men were exceedingly susceptible to the lure of alcohol. The North American Indians when afforded opportunity, not only drank furiously, but were furious when drunk. As a rule men were moderate or immoderate in proportion to their susceptibility to the charm of alcohol. The point, however, that Reid insists on is that every race is resistant to the effects of alcohol in proportion to the length and severity of its past experience of alcohol. When governments tried to enforce prohibition they entered into a fight against Nature in which they were always beaten in the long run. Professor Starling, the great British physiologist, has brought out a book recently to which many well known medical scientific men have contributed, in which moderate drinking is upheld. Excess is reprobated and admitted to be most harmful by all but the consumption of alcoholic beverages in strict moderation appears to be believed by many authorities to do more good than harm.

THE EVOLUTION OF DIET.

Dr. Harry Campbell is the first authority in this country on the evolution of diet or evolution and diet. On October 23d he gave a lecture on the subject at the Institute of Hygiene in London in which he denied some popular beliefs as to the diet of early man. Early man is generally pictured as surrounded by a profusion of sweet tasting seeds and luscious fruits in an Eden of plenty, with merely the trouble of plucking them. According to Dr. Campbell the fact was that during the earliest period man's diet included all sorts of animal food from fish, birds, birds' eggs and every species of mammal down to frogs, lizards, snakes, shellfish, worms, snails, insects, caterpillars and grubs. Honey was available, while seeds and nuts provided protein food, fruits gave carbohydrates and salts, and fleshy vegetables gave starch. There were also berries, leaves and shoots. After the anthropoid period man became more intelligent and nomadic. He could trap small animals, and was able to reject, to some extent, the less palatable and indigestible vegetables. Then came the period when man learned to hunt and fish. Better supplies of animal food led to its greater use, with a subsequent lessening of the ability to digest raw vegetables. Cookery, which came next, was probably the most epoch making of all discoveries, for with it man secured the master key to limitless supplies of food, especially starchy forms. Starch foods were now consumed to an enormous extent and in a pappy form which could be swallowed without mastication. The modern diet was literally deluged with starchy foods which slipped down the gastrointestinal tract with a facility which could only be characterized as disastrous. Man had accordingly passed from vegetarianism to a mixed diet which tended to revert to vegetarianism. Man was less able to digest raw vegetables, but a race was being evolved capable of being reared on cow's milk and of digesting enormous quantities of starch and sugar. Dr. Campbell concluded by saying that it was incorrect to assume that disease and premature death resulted from animal food as man was for a long time more carnivorous than vegetarian.

ADDRESS BY DR. J. A. FORDYCE OF NEW YORK.

A special meeting of the Section of Dermatology of the Royal Society of Medicine was held in the house of the society on October 18th; Dr. E. Graham Little, the president of the section, was in the chair, to hear an address by Dr. J. A. Fordyce, of Columbia University, New York. The subject of the address was the results of treatment of syphilis of the nervous system. For the purpose of comparative study Dr. Fordyce and his colleagues had grouped their 442 cases under the following tentative diagnoses, based on the clinical and laboratory findings: 1. Secondary neurosyphilis; 2, vascular and moningovascular; 3, pretabes or tabes imperfecta; 4, tabes well developed; 5, optic atrophy and general paralysis. Three hundred and sixty-five of the 442 cases had been examined from one to ten years after treatment had been discontinued. Ninteen cases of secondary neurosyphilis were treated intraspinally because of the persistence of their symptoms and the fact that there were fluid findings after from one to three doses of salvarsan given intravenously and mercury intramuscularly. Wassermann was positive in all cases either in the blood or in the fluid; in a large majority in both. The cell count ranged from normal to 940. Five of the nineteen cases received more than one dose of combined intravenous and intraspinal treatment; eight had more than two doses; five had more than three doses. In all the nineteen, the headache, insomnia, vertigo, aphasia, and facial palsy disappeared. Those which had marked tendon and papillary changes had them still. In every case the reaction became negative in the blood, and in only two cases remained weakly positive in the fluid. Of 116 cases of paresis treated intensively 39 died, 30 had passed from observation, and 47 were known to be still living. He could not report any cures, though remissions were induced in 46 patients, the intervals lasting from a few months to several years. Before he left New York treatment had been begun with the new arsenical preparation tryparsamid in a number of paretics; he could not yet pronounce as to its value.

Dr. Fordyce summarized his conclusions as follows: The central nervous system is mostly invaded during the general dissemination of the virus. Often it was checked, seldom cured, by the usual therapeutic methods. Late neurosyphilis is not due to reinfection from foci, outside the nervous system, but to long persistence in loco of the infecting organism. If the nervous system was not involved early in the infection, probably it would not be involved later; this with the exception of vascular lesions and gummata. In the presence of a persistent Wassermann, the possibility of a nervous system lesion, should be borne in mind. Treatment should not be stopped without the information that could be gained from lumbar puncture. Certain types of nerve syphilis were more rapidly controlled by combined intravenous and intraspinal treatment, and sometimes only by this method. In general paralysis remissions of long duration were achieved which were more striking in patients with a pronounced meningeal reaction.

In the general discussion which followed, Dr. J. H. Sequeira pointed out that the work done long ago by Head, Fearnsides and others showed that the spinal cord and brain were affected in very early stages of syphilis. All the available knowledge showed how important it was to commence treatment for syphilis at the earliest possible moment. Dr. H. MacCormac remarked that it might be said the neurologist saw the failures of the dermatologist in this disease.

BOOK ON GIRTH CONTROL TO BE PUBLISHED.

A book on *Girth Control, the Cure of Obesity and Constipation*, by F. A. Hornibrook, with a preface by Sir William Arbuthnot Lane, will be published soon by William Heinemann, Ltd., London.

LATIN AMERICAN LETTER

(*From our own correspondent.*)

BALBOA HEIGHTS, *November 2, 1923.*

MARITIME QUARANTINE CONFERENCE.

The chief quarantine officer of the Panama Canal, Surgeon W. C. Rucker, U. S. P. H. S., returned from the United States on October 20th and immediately took up the completion of the plans for the conference of the Maritime Quarantine Authorities of the West Coast of South America. This conference, which has for its object the standardization of maritime quarantine on the western coast of South America, has been called by President Belisario Porras to meet in Panama City, R. P., on January 8, 1924. Representatives from Panama, Colombia, Ecuador, Peru and Chile will attend. Surgeon General H. S. Cumming and assistant Surgeon General John D. Long will attend the meeting on behalf of the United States Public Health Service, and Colonel H. C. Fisher, M. C., U. S. A., chief health officer of the Panama Canal, will represent his department. While a large attendance at this meeting is not expected or aimed at, its results will be farreaching in the rationalization of quarantine and in expediting the movements of ships, cargoes and passengers.

There is little doubt that many of the practices of quarantine are archaic in view of our modern knowledge of the means of transmission of disease and the rapid means of travel and communication which the world now has. Diseases which were once a very genuine menace to the welfare of the United States have been freed of their terrors by scientific research. Yellow fever now exists in only two localities in the western hemisphere; typhus (to continue the enumeration of the quarantinable diseases) is almost always present in New York City yet does not spread because of the bathtub; smallpox is easily prevented; for the most part, human beings play a relatively small rôle in the spread of bubonic plague; cholera would have small chance of spreading in a country in which typhoid fever is of relatively rare occurrence; and leprosy, the last of the diseases mentioned in the quarantine disease act, is known to be conveyed only by prolonged, intimate contact. Thus, so far as the United States and the Panama Canal are concerned, a considerable amelioration of quarantine might take place without harm to public health. However, there are many countries in a less fortunate sanitary condition and any abatement of the barriers against disease incursion might result in disaster. Therefore, any changes in the international quarantine regulations require farreaching thought and that enlightenment which comes from face to face discussion. The quarantine regulations of most countries contain much dead wood and senseless verbiage designed to "shoot if it's a deer and miss if it's a calf." Many things are being done under the guise of quarantine "because they always have been done," others because quarantine regulations do not always authorize quarantine officers to exercise that judgment which scientific men now have with regard to disease and still others because of that dread of change which is the heritage of all mankind. Conferences like that to be held at Panama are therefore of the greatest value in modernizing and rationalizing maritime quarantine.

COMBATTING YELLOW FEVER.

Dr. Henry Hanson, of the International Health Board, is in Panama purchasing office equipment for the central offices which he is establishing at Barranquilla, Colombia. Dr. Hanson is the director of the campaign against yellow fever in the Republic of Colombia and is assisted in this work by Dr. Frederick A. Miller and by L. H. Dunn, entomologist, and G. W. Stuart, sanitary engineer. Eradicative work has been begun at Bucaramanga and preventive campaigns have been launched at Cucutá, Girardot, Puerto Berrio, Barranca Bemeja and Puerto Wilches. These are all interior towns and are in the general littoral of Santander Province where the yellow fever epidemic early in 1923 occurred. Work will also be conducted at Cartagena and Santa Marta on the seacoast and at all ports on the Magdalena River, the main travel route of the republic. Illustrative of the degree of mosquito infestation which is being met, Dr. Sainz, one of Dr. Hanson's medical inspectors, visited 959 houses in Barranquilla and discovered mosquito breeding in 949. He was not able to determine accurately the presence or absence of larvæ in the other ten on account of the turbidity of the water! He obtained practically the same results in Puerto Columbia. This campaign represents practically the last stand of yellow fever in northern South America. The last case of the disease in Panama was in 1905, in Ecuador in 1919, in Peru in 1921 and in Mexico on January 15, 1923. With the giantic eradicative campaign which is being launched at Bahia, Brazil, under the direction of that veteran warrior against pestilence, Dr. J. H. White, yellow fever will soon be an extinct disease in the western hemisphere.

ISTHMIAN CANAL ZONE MEDICAL MEETING.

The 202nd meeting of the Medical Association of the Isthmian Canal Zone was held at Colon Hospital on October 19, 1923. The members from the Panama (Pacific) side of the Isthmus made the journey to and from Colon by track motor. The following program was presented: Presentation of case of perforated peptic ulcer, with recovery, by Dr. Tom S. Mebane; remarks on cases of clinical interest treated at Colon Hospital: Acute rheumatic fever in the negro, myocarditis with advanced cardiac decompensation with complete and permanent restoration of function, angina pectoris and auricular fibrillation with restoration of normal rhythm by quinidine, and a case of ruptured uterus during labor, by Dr. W. V. Levy; lengthening of the quadriceps in extraarticular ankylosis of the knee joint, treatment of head injuries and an analysis of eighty cases of appendicitis treated at Colon Hospital during the past year, by Dr. T. S. Mebane.

It is believed that the cures which are being made at the Palo Seco Leper Colony are the cause of the increased admissions from the interior of the Republic of Panama to that institution. On July 23rd there were fifty-eight males and twenty-seven females in the institution. Treatment with the ethyl esters of chaulmoogra oil is being administered by Dr. Philip Horwitz. With the exception of those patients who have died or who have been returned to the Colony for treatment, there have been eighteen paroles since September 3, 1914. Five of these were granted during 1923.

NEW HOSPITALS FOR PANAMA.

The Republic of Panama has inaugurated five thirty bed hospitals in various parts of the interior. These are under the direction of Santo Tomas Hospital of Panama City, of which Major E. A. Bocock, M. C., U. S. A., is superintendent. These hospitals are located at Colon, Bocas del Toro, David, Santiago and Chitré, each being in the principal town of its Province. These are really the outgrowth of old hospitals located at the same places and will be remodeled and modernized both as to buildings and equipment. They are designed to care for cases requiring short treatment, minor injuries and minor surgical operations. All complicated cases and those which will require treatment over a considerable stretch of time will be sent to the main hospital, i. e., Santo Tomas. It is hoped that each of these branch hospitals will in time become health centres for their respective provinces. All charges for maintenance will be paid by Santo Tomas out of funds set aside for the purpose by the central government.

OCCUPATIONAL AIDE FOR INSANE HOSPITAL.

As an extension of the work of occupational therapy introduced by Dr. Louis Wender, former superintendent of Corozal (Insane) Hospital, the present superintendent, Captain G. E. Hesner, M. C., U. S. A., recommended to the chief health officer the employment of an occupational aide. This recommendation was approved and through the assistance of the National Committee for Mental Hygiene, a suitable appointee has been secured and will sail shortly from the United States.

RAT POISONS PROHIBITED.

The discovery of organisms of the paratyphoid group in samples of rat poison submitted to the laboratory of the health department for examination has resulted in the prohibition of the sale of such products in the cities of Colon and Panama.

BOTTLED MILK ONLY FOR ZONE.

The Health Depatrment of the Panama Canal has received a shipment of 20,000 milk bottles which will be sold at cost to the milk dealers of Colon and Panama in order to insure that only bottled milk will be sold in the terminal cities and in the Canal Zone.

MEDICAL STAFF ADDITIONS.

Recent additions to the medical staff of the Panama Canal are Captain Henry J. Hayes, M. C., U. S. A., who as been assigned to duty at Corozal Hospital, and Major J. M. White, M. C., U. S. A., who has taken up his work at Ancon Hospital. Lt. Col. S. J. Morris, M. C., U. S. A., has reported for duty as department medical inspector and assistant to the department surgeon, Colonel Henry Webber, M. C., U. S. A.

WEEKLY CLINICAL MEETINGS AT ANCON HOSPITAL.

Physicians and surgeons visiting the Isthmus should bear in mind the weekly clinical meetings which are held at Ancon Hospital Thursdays from 11 to 12 a. m. Many interesting cases are shown and demonstrations of the newer clinical laboratory tests given. Once a month there is a journal review at which resumés of recent medical literature are presented. Medical visitors are always welcome and they will find much to interest them there. The attendance at the clinical meetings is representative of the medical corps of the army, navy and public health service as well as of the health department of the Panama Canal and the local medical profession, and visitors at the clinical conferences will thus have an opportunity to meet a number of those who are doing medical work in Panama.

GENEVA LETTER

(*From our own correspondent*).

GENEVA, *September 15, 1923.*

ENTAMEBA AND SPIROCHETA IN PYORRHEA.

The entameba gingivalis has been regarded as the cause, or one of the causes, of alveolar pyorrhea by many observers in Russia, the United States, Italy, France, Switzerland and Germany. Alveolar pyorrhea is such an important morbid process from both the medical and surgical viewpoints, that all new data on the subject can never be devoid of interest. Therefore a short account of some research work, undertaken recently at Lausanne by D. Zouraboff, should be enlightening.

Bass and Barrett conclude that the entameba gingivalis is found in every mouth but not constantly and they are more numerous in cases of gingivitis. They are, however, of the opinion that this organism is not the cause of alveolar pyorrhea.

Upon what do the partisans of the specific pathogenic part played by this ameba base their assertions? First, its presence in alveolar pyorrhea; in point of fact, it is not always found. Secondly, on its absense in healthy mouths. There are cases, twenty-nine per cent. in the researches of Wessels, Williams, von Scholly, Rosenberg and Mann, and forty-one per cent. in Mendel's, where the organism was found in perfectly healthy mouths with normal gums. Thirdly, the results of treatment with emetine hydrochloride, although, besides the good results, completely negative results have been obtained from its use. For example, Mendel having made instillations in the purulent pockets and intragingival injections with this drug found that in eight cases of pyorrhea it was a complete failure. Ruoff treated 187 cases of pyorrhea with extract of ipecac fluid and emetine hydrochloride and noted a temporary disappearance of the amebæ and their reappearance within two to three weeks. This observer concludes that emetine is an amebicide but it is incapable in itself of curing alveolar pyorrhea.

TREATMENT OF PYORRHEA.

In the majority of cases of this disease, besides the ameba when it is present, there are numerous spirocheta and it is to be noted that in these circumstances many cases of pyorrhea are cured after a time by the various arsenical compounds now so generally used in syphilis. They appear to have a specific action on these buccal spirochetes. This has been confirmed recently by Kolle who treated an enormous number of cases in the German army in 1918, and observed that the pyorrhea was in all probability produced by the spirocheta dentium which he found in almost pure cultures.

Given the fact that the entameba gingivalis had only been found once in 1916, at Lausanne, by Prof. Galli-Valerio and as both American and French observers have lately given considerable attention to this buccal parasite and the part played by it in alveolar pyorrhea, Zouraboff at Lausanne took up the subject with the view of discovering the frequency of the entameba gingivalis as well as its probable etiological part in the production of pyorrhea. The white substance covering the neck of the tooth was removed on a wooden toothpick and spread on a cover glass. When dried in the air it was treated with methyl alcohol. For each case four slides were prepared. Upon several occasions Zouraboff essayed staining the preparations with Giemsa, diluted 1 in 20, and although they were allowed to remain for fifteen or twenty minutes, even six hours, a bad result was invariably obtained; the bacteria, epithelial cells and leucocytes were all stained pale and the stain was diffuse. This observer has never been able to discover ameba or spirocheta dentium by means of this rapid staining process.

COMPARATIVE STATISTICS.

In Mendel's statistics gathered at Paris, the ameba was found in 95 per cent. of the cases, while those of Wessels, Williams, von Scholly, Rosenberg and Mann give 60 per cent. Therefore at Lausanne the entameba gingivalis is relatively less frequent in pyorrhea than in Paris and the United States, the only countries offering statistics. In Germany, according to Hartmann and Schilling, the organism exists in the majority of the people.

A much greater difference is shown if the frequency of ameba in subjects without pyorrhea or gingivitis is compared. Of forty-two subjects with healthy gums in only one did Zouraboff discover it—2.4 per cent., while Mendel found it in forty-one per cent. and Wessels, Williams, von Scholly, Rosenberg and Mann in twenty-nine per cent. Starting from the fact that amebæ were absent in fifty-one per cent. of the pyorrhea cases he examined, that in one patient treated with emetine the gingivitis remained although the ameba disappeared, and that in the majority of cases of pyorrhea the organism was associated with the spirocheta dentium, Zouraboff concludes that the entameba gingivalis is merely an accidental parasite of pyorrhea and gingivitis, developing on a favorable soil. He also points out that this is also confirmed by the results obtained with 606 and the almost constant presence of the spirocheta dentium. This speaks in favor of the pathogenic part played by this parasite in this morbid process..

ENTAMEBA IN GOITRE.

Evans recently searched for the entameba gingivalis in the tonsils of goitrous subjects and found it in ninety seven per cent. of the cases. In eighty-one per cent., the patients treated with emetine hydrochlorate and afterwards examined showed that the organism had disappeared. He then exhibited emetine to twenty-three subjects with goitre, with the result that the tumor was reduced in size in eighteen.

Zouraboff examined ten cases of goitre but was unable to observe any ameba or spirocheta in the smears taken from the substance coating the tonsils. Although the cases were few as compared with Evans, the Lausanne observer, thinks that his results speak against any pathogenic part played by entameba gingivalis in the production of goitre.

Book Reviews

DIET

Anleitung für die Ernährung von Zuckerkranken mit praktischen Anweisungen für die Diabetesküche (nach weiland Dr. Gilbert's *Diabetesküche* und weiland Prof. Dr. *Albert Albu's Grundzüge für die Ernährung von Zuckerkranken*), bearbeitet von Dr. med. Edwin Silbermann. Mit einem Vorwort von Geh. Rat Prof. Dr. H. Strauss, Berlin, Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1923.

This little handbook is a successor of similar books by Gilbert and Albu. It is intended to give the diabetic laymen instruction in the preparation and selection of his food. It teaches him that carbohydrates must be more or less eliminated from the diet according to his needs. In some cases the proteins are also restricted. Fats and vegetables poor in carbohydrates, especially the green vegetables and salads, should constitute the mainstay of the diabetic diet. Careful medical observation and the strictest carrying out of the physician's orders are absolutely necessary. The ingredients and the manner of preparation of all the dishes are described minutely. With this booklet in his hands the diabetic patient need never become tired of his diet as there is an abundant choice from which to choose.

DIET

What to Eat and How to Prepare It. By Elizabeth A. Monaghan. New York: George H. Doran Co., 1922.

A very simple little volume on the relation of food to health. The author states that her work is the outgrowth of Alfred W. McCann's *The Science of Eating,* and the book takes its place as a member of the younger set of books on the subject of food in health. Miss Monaghan writes in an easy jocular vein, the effect of which is heightened by large type and generous paragraphing. Part II on Preparing the Food is valuable. The recipes are clear and comprehensive. There is another valuable chapter containing menus for anemic, undernourished or convalescent people that ought to be a boon for nurses and those having sick ones in the home. Children's diet is given some attention and a chapter for the girl who works contains a lot of good information and practical hints.

THE EYES

Ophthalmic Surgery. A Handbook of the Surgical Operations on the Eyeball and Its Appendages as Practised at the Eye Clinic, University of Vienna, by Dr. Josef Meller. Edited by Dr. William M. Sweet. Third Edition Translated from the Second Edition, *Augenaerztliche Eingriffe* (Josef Safar, Vienna). With 219 Original Illustrations. Philadelphia: P. Blakiston's Son and Company. 1923.

The third edition of this deservedly popular work has been enlarged by over seventy pages of reading matter, and by forty-six very interesting illustrations. The period of ten years intervening between this and the preceding edition has not been particularly productive of great changes or any marked discoveries in the operative domain of the eye, barring, of course, the plastic work resulting from the experiences of the Great War; though even for this the time is not yet ripe to formulate a definite opinion. Whatever of interest and permanent value did find its way into practice during this period has been incorporated in this work which has been thoroughly rearranged, rewritten and considerably enlarged, as, for instance, the entire chapter on cicatricial entropion; additional paragraphs on spastic entropion; a great deal of additional matter on operations on the orbit; extraction of foreign bodies from the eye; certain notes on local anesthesia for enucleation, etc. Of especial interest are the additional subjects on Elliott's sclerocorneal trephining that is dealt with at considerable length, and treatment of detachment of the retina to which almost six pages are devoted as contrasted with the few lines in the preceding edition.

The possessors of the former edition will find this one interesting for its additional contents. In the hands of its first readers it is sure to become a valuable guide in all their operative work on the eye. A certain tragic touch, of undoubted human interest to the American reader, is imparted to the book by its author's dedication to the "Rockefeller Foundation With Feelings of the Deepest Gratitude for the Magnificent and Noble Support, in the Years of Distress, it Granted the Medical Faculties of the Austrian Universities."

CONFESSIONS OF A PSYCHOLOGIST

Life and Confessions of a Psychologist. The Autobiography of G. Stanley Hall, Ph.D., LL.D. New York: Appleton & Company, 1923.

It was that he might truly know himself that Dr. Hall set down this fascinating record of a life. The childhood background, the parents, their interests and conflicts, all the factors that were to mould the youth, are understood and objectified. There is none of the just personal pride in the achievements of his life time, save what any man might feel in looking at the solid bulk of work accomplished. The storehouse of a productive thinker's mind has been probed, emotions, opinions, experiences and beliefs turned over and looked at dispassionately, above all, honestly. The history of education in this country, spanned by the life of the greatest living American psychologist, is a history that is singularly one with the man. He is the history of education. Without him it might well have had no history—and no historian.

PHANTASY

Deirdre. By James Stephens. New York: The Macmillan Company, 1923.

Rarely does an age old song come down to us intact. Of course it is our fault. The songs are there, but only for the few whose pulses thrill to that type of literature. In general the denizens of *Main Street* respond to the urge of "Jazz her up," and "Make it snappy."

In *Deirdre,* Stephens has sung a harper's lay in his own mellow words, preserving that clear conciseness of thought and image, crisp and yet gladdening as a spring breeze. The old story of the beautiful ward of a king, who follows her heart's choice through countless perils and finally to death is as real to us, and as tragically beautiful, as when the legendary characters were first caught in the web of love and reality. A vague memory of Synge's poem, Deirdre of the Sorrows, serves to fix the tradition in our minds, studded as it was with gleaming pictures and the music of echoing words. Stephens's *Deirdre* steps on to the scene and *is* Beauty, Music, Life and Tragedy.

Medicoliterary Notes.

Since the incidence of diphtheria in the Borough of Richmond was relatively greater than that in any other borough, the New York City Department of Health made a survey of the records of all cases reported from January 1st to August 15th inclusive. The findings of this survey testified in a significant way to the value of the Schick test. The largest school district, with an estimated population of twenty thousand, had only sixteen cases, while the next to the largest, with a population of seventeen thousand, had sixty-nine cases. The larger district had had thorough Schick work done in its schools, while the other, in which the cases were most numerous, has only one public school of fair registration and a parochial school, in neither of which had any of this work been done.

The publication of a collection of studies, based upon personal investigation, by Frank Tannenbaum, of social conditions in the South, including the prison problem and the Ku Klux Klan, has been announced by Putnam for the early spring.

* * *

A recent volume from the Johns Hopkins Press is entitled *The Public Health Service: Its History, Activities and Organizations.* The author is Laurence E. Schmeckbier.

* * *

A Medical Dictionary for Nurses, compiled and edited by Amy E. Pope, has recently been put on the market by Putnam. It is a compact volume of less than three hundred pages, but is fairly comprehensive in scope. It gives definitions, derivation and pronunciation, and has supplementary tables of weights and measures, chemical symbols, and other material.

* * *

In the *Century* for November Glenn Frank has an entertaining article entitled Sackcloth and Cymbals. His belief is that "the whole world today is in a mood of transient hysteria. And this hysteria is only another way of saying that the world is wool gathering." The writer discusses also H. G. Wells's opinion that we are about to cast off our "sackcloth" and enter upon an era of humor; the new Dark Ages predicted by Dean Inge of London; and the possibilities of a coming renaissance prophesied by other writers of the day.

* * *

The University of the State of New York has prescribed for pupil nurses in the senior year of training schools a course of lectures on public sanitation. The purpose is "to give the nurse a general practical knowledge of the methods which are being used to protect the health of individuals and communities, so that she may cooperate practically with boards of health and other preventive agencies, and be able to take a definite share in educating the public in matters relating to public health." Some of the subjects to be covered are sources and modes of infection, sewage and garbage disposal, water and food supply and ice, ventilation and housing, industrial hygiene, hygiene of schools, public buildings, and conveyances, vital statistics, and health departments and legislation.

* * *

The October number of the *Medical Brief,* published in St. Louis, contains two articles of particular interest: a full story of insulin and its discovery, by J. J. R. McLeod, professor of physiology in the University of Toronto; and a reprint of the address on The Psychoses, given by Dr. Edwin Goodall, medical superintendent of Cardiff Mental Hospital, at the July meeting of the Medico-Psychological Association of Great Britain and Ireland.

* * *

The fourth series of Frank Harris's *Contemporary Portraits* is announced by Brentano's for publication in the near future. The volume is done in the author's characteristic style, and will include sketches of Matisse, Turgenief, Leonard Merrick, Senator La Follette, Charlie Chaplin, and Richard Wagner.

* * *

An interesting fact about the practice of medicine in China is to be found in a recent report of Prof. W. D. Matthew, curator of the Department of Vertebrate Paleontology at the American Museum of Natural History. The report states that in China fossil teeth and bones are used as medicine, and have been mined for centuries to supply Chinese drug stores with "dragon's bones" and "dragon's teeth." "There are four ways of administering them. They may be ground to powder in a mortar and eaten raw. Or they may be ground and fried with oil in a skillet. Or the powder may be stirred up with sour wine and either drunk off fresh or the mixture left to settle, decanted, and the clear liquid drunk. They are a specific for certain nervous diseases, heart troubles and disorders of the liver. Without recommending the remedy for adoption in this country, it is perhaps permissible to point out that mixing with sour wine would result in a combination of bicarbonate and acid phosphate of lime that might really have some medicinal value, just what may be left to physicians to decide."

* * *

An article on dust and its sources in a recent issue of the *Popular Science Monthly* states that the most spectacular source is the dust storm, in which the soil of dry areas is carried overland by high winds for many miles. The greatest dust fall ever recorded was in 1920, when, it was estimated, two million tons of the soil of Colorado, Wyoming, Kansas and Nebraska was lifted many thousand feet and carried by a fierce wind storm into the region of the Great Lakes and the St. Lawrence, where it was deposited in the form of dust particles during a snow storm lasting only two days.

A study recently made by the Rockefeller Foundation shows that the United States has the largest number of medical schools of any country in the world—eighty-two. Great Britain has forty-three, France thirty-two, and Russia twenty-eight.

Practical Therapeutics

ON THE VALUE OF THE RÖNTGEN RAY IN THE DIAGNOSIS OF CHRONIC APPENDICITIS*

By Maurice Feldman, M. D.,
Baltimore, Md.,
Instructor in Gastroenterology, University of Maryland.

The difficulty in the diagnosis of chronic appendicitis at times is well recognized. This is not only due, often to the frequent occurrence of this affection without the usual clinical manifestations ordinarily observed in this disease, but also because of the occurrence of other lesions which may present themselves in the lower right quadrant. These difficulties may now often be overcome by means of the x ray, which affords us a means of more thoroughly clearing up the diagnosis in obscure cases.

In the röntgen ray diagnosis of chronic appendicitis the most valuable information upon which a correct diagnosis may be based, is found in the definite anatomical and pathological changes observed in the appendix itself. On the other hand, the indirect signs in the diagnosis of this disease are most helpful and are especially valuable when confirmed by clinical findings; while the diagnosis is often misleading when based upon insufficient röntgen signs or faulty interpretation.

A negative röntgen ray result may be helpful to the clinician in differentiating disease of the stomach and duodenum from right lower quadrant lesions. A differential diagnosis must be made from gastric and duodenal ulcer, gallbladder disease, right kidney, ureteral and pelvic affections. Again it may be important to distinguish chronic lesions of the appendix from other affections commonly occurring in the lower right quadrant, as dilatation of the cecum with retention, an incompetent iliocecal valve and ileal stasis, adhesions and angulations, as well as ulcerations due to carcinoma or tuberculosis.

In the diagnosis of chronic appendicitis, the following direct and indirect signs must be taken into consideration.

DIRECT SIGNS.

1. Visualization of the appendix. The percentage of visualized appendices varies with the technic according to the various observers. According to our method purgation is not permitted for at least twenty-four hours before the examination. Spriggs and Marxer state that the appendix is most frequently visualized when the bowels had been emptied by castor oil given thirty-six hours before the opaque meal of barium and buttermilk. Other observers prefer the patient in a constipated state.

2. The appendix is regarded as suspicious when found retrocecal or directed upward. It may be directed downward or to the left side.

3. The normal calibre of the appendix is one sixteenth to one quarter of an inch in diameter. In diseased conditions it may be found much dilated.

4. A tender area observed directly over the appendix and moving with it, is an important röntgen sign of disease of this organ. Of 273 cases reported by Case in which the appendix was filled with bismuth, there was a definite tenderness corresponding to the appendix shadow in 236 or eighty-five per cent.

5. The appendix should normally empty coincidently with the cecum. A delay in emptying beyond this period may be regarded as pathological. In general any appendix revealing a retention of twenty-four hours following the emptying of the cecum may be regarded as suspicious. According to other observers a period of forty-eight hours is regarded as pathological. Case reports an instance of retention of twenty days; but longer periods have been noted. The longer the retention, the more certain are we of disease of the appendix.

6. The usual length varies from one half to nine inches, the average being three inches. An unusually long appendix is more likely to be diseased on account of its poor drainage.

7. The appendix is normally free, when diseased it may be fixed in the iliac fossa, retrocecal, in the pelvis, adherent to the gallbladder, sigmoid, transverse colon or rectum. Fixation of the appendix is pathognomonic of a pathological state of this organ.

8. Irregularities of the lumen, if constant, are significant of disease.

9. Kinks when constantly noted suggest a pathological appendix.

10. Concretions are best examined before the administration of an opaque meal. They are always an indication of disease.

In a large percentage of cases, the appendix cannot be visualized and on this account the diagnosis must be made by means of a group of indirect signs.

INDIRECT SIGNS.

1. The cecum organ is normally freely movable, appearing as a blind pouch, lying in the right iliac fossa. It may be fixed in the iliac fossa, right pelvis, to the transverse colon, sigmoid or rectum. Fixation suggests disease or postoperative adhesions.

2. Cecal stasis is not an unusual finding and is more significant when the other portions of the intestinal tract are empty.

3. Dilatation of the cecum suggests an inflammatory process or obstruction in the region of the ascending colon or hepatic flexure due to tumor or adhesions.

4. A tender area over the cecum at the position from which the appendix arises, when the appendix is not visualized, suggests the possibility of a diseased appendix.

5. Stomach peristalsis may be normal or active. It is frequently active, the stomach being pulled down into the region of the lower right quadrant. Pylorospasm or gastrospasm are frequently noted, and occasionally six hour retention may be observed due to spasm of the pylorus.

6. A spastic colon is frequently noted in chronic appendicitis. This finding may however be due to other conditions.

7. A large percentage of our cases presented a prolapsed colon, which may account perhaps for the

---

*From the Gastroenterological Clinic of the Department of Medicine, University of Maryland.

low grade inflammatory process of the appendix, possibly produced by stasis.

The appendix is best studied with the patient both in the erect and recumbent posture; special attention and care being taken to palpate and manipulate the lower right quadrant area, in order to visualize the appendix under the fluoroscope. On this account the fluoroscope offers us the best method of examination. The special points to be noted are the mobility of both the appendix and cecum, and the tender point. A film is usually made for finer detail and record. At times the appendix may be noted under the fluoroscope, yet may not be observed on the film. This is usually due to position, the appendix being overshadowed by the cecum, ileum or colon.

The terminal ileum at times resembles the appendix and may mislead the röntgenologist. We have recently noted this in one instance; a definite tender point was elicited over the terminal ileum, the appendix having been removed some years previous to the examination.

The appendix is best visualized in from six to twenty-four hours after the barium meal. Skinner states that forty-eight hours is the most favorable period for this examination. We cannot lay too great stress upon the fact that visualization itself does not always necessarily denote a diseased appendix. The röntgenologist's report in these cases must be conservative and unbiased.

The appendix arises normally from the inner and posterior side of the cecum below and behind the terminal ileum, corresponding to McBurney's point on the abdominal wall when the patient is in the recumbent posture, and is lower in the iliac fossa in the erect position.

In pathological conditions involving the lower right quadrant in which the appendix and cecum are fixed by adhesions, this relation of McBurney's point and the appendix is altered. Instead of obtaining the typical localized tenderness over McBurney's point the tenderness is elicited low down in the right lower quadrant, perhaps even in the pelvis or to the left side.

The relation of the duodenum to McBurney's point has often caused errors in diagnosis. On account of the position of the duodenum which is normally somewhat to the right of the midline, the tender point noted in duodenal ulcer may be mistaken for that of a chronic appendicitis. It not uncommonly occurs, that patients present themselves at our clinic on whom appendectomies had been performed without relief, and reveal the typical signs and symptoms of duodenal ulcer; while on the other hand it is not unusual to note that patients present symptoms of duodenal ulcer in whom upon röntgen examination the duodenal cap appears normal while the appendix is found diseased.

It is well to bear in mind that by no means can the conclusions be drawn that simply because an appendix is observed to be in a pathological state as is indicated by an x ray examination, that it should be removed. According to our observation, not until distinct clinical manifestations are observed should operation be advised.

On the other hand it is of importance to bear in mind the necessity of a routine röntgen examination in all chronic gastrointestinal affections, especially before operative procedures are undertaken in order to rule out a diseased appendix.

In a recent series of fifty-five cases in which the diagnosis of chronic appendicitis was made by means of the röntgen ray, the conclusions arrived at clinically were as follows: twenty-five cases were confirmed clinically, five of which were proved by operation; there were nineteen cases which were diagnosed as enteroptosis, three as peptic ulcers, five as gall-bladder disease, and one as colitis.

This series, though small, illustrates the fact that the clinical manifestations do not in a large percentage of cases corroborate the röntgen diagnosis. The nineteen cases of enteroptosis presented a group with vague symptoms not referable to the appendix itself. As enteroptosis is a common finding in our series, I am inclined to believe that it often predisposes to a low grade inflammation of the appendix, which may produce but few symptoms referable to the appendix.

CONCLUSIONS.

1. Röntgen examination in chronic appendicitis is best based upon anatomical and pathological findings.
2. Indirect signs are helpful, especially when the appendix is not visualized, but these should always be corroborated clinically. Insufficient röntgen signs and faulty interpretation are misleading while conservative interpretation is however of great value to the clinician.
3. Röntgen examination does not always eliminate the presence of a chronic appendicitis, and again röntgen signs of disease may be observed without clinical manifestations.
4. The presence of chronic appendicitis as noted by röntgen ray examination does not by any means always indicate the necessity for surgical intervention.

Metabolic Disturbances of Pregnancy.—Paul Rissmann (*Zentralblatt für Gynäkologie*, August 26, 1922), by analyzing the blood in cases of disturbed metabolism in pregnancy, found that the mother is deprived of calcium by the fetus and that the maternal blood is deficient in calcium in nephritis and in eclampsia. Inasmuch as the maternal blood also shows a diminished alkalinity, and as the total amount of potassium in the body is three times as great as the amount of the sodium and the amount of calcium is forty times as great as that of magnesia, the author administered sodium and potassium salts in the metabolic disturbances of pregnancy. No special diet and no rest in bed was ordered. There was no albuminuria and severe metabolic diseases (eclampsia with or without convulsions) were never observed. Most of the symptoms were either entirely cured or they were reduced in severity.

Proceedings of Societies

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS, AND ABDOMINAL SURGEONS.

Thirty-fifth Annual Meeting, Held in Albany, N. Y., September 19, 20 *and* 21, 1922.

The President, Dr. Roland E. Skeel, in the Chair.

(*Concluded from page* 595.)

Routine Treatment for Hyperemesis Gravidarum.—Dr. Edward Speidel, of Louisville, Ky., stated that a definite treatment should be followed in these cases so that improvement might be determined by the available chemical tests and where laboratory facilities were not at hand the failure of the treatment would be the indication for interruption of the pregnancy. The routine treatment consisted of the daily administration per rectum of a solution containing glucose, panopeptone, sodium bicarbonate and water. Sodium bromide and chloral were added according to indications. Every third day 500 c.c. of ten per cent sterile glucose solution was given intravenously. The glucose not only relieved the carbohydrate deficiency, but would be absorbed directly by the liver and would aid in regenerating the liver cells damaged by the toxemia, if the destruction had not gone too far. Gastric lavage was practised on the eighth day and oral administration of food was begun on the ninth. If the patient vomited in spite of this rigid régime interruption of pregnancy would be necessary.

Study of Urinary Tract of Eighty Fetuses and Infants.—Dr. George Van Amber Brown, of Detroit, Mich., stated that evidence of chronicity became apparent at an early age, even in the early months of fetal life. Bloodvessel involvement was not a constant accompaniment of luetic changes in early life. Kidney hemorrhages, both primary and secondary, were not rare in fetuses and young infants. Fetal kidney inflammatory changes might be either acute or chronic, primary or secondary, infectious or noninfectious. Malignant kidney tumors of sarcomatus nature were seen during the very early months of life. Renal calculus occurred in early life. The kidney in his opinion manufactured urine months before maturity of fetus, and probably in considerable quantity; also the fetus might develop a toxemia from retention, in its blood stream of kidney products independent of the blood stream or kidney efficiency of the mother. There apparently was a close relationship between kidney and brain in their development, and between brain and adrenals.

Renal Tuberculosis: Diagnosis and Treatment.—Dr. Henry Dawson Furniss, of New York, said that the accepted treatment for unilateral renal tuberculosis was nephrectomy, providing there was no contraindication in other concurrent disease or renal insufficiency. The earlier the disease was eradicated, the better the chances of preventing further spread and of relieving the bladder condition. With bilateral involvement some authorities had advocated removal of the kidney with the more advanced lesion. This did not seem warranted unless the better kidney had only slight lesions with good function and its ureter with the part of the bladder surrounding it was not involved. Even then, unless the patient was suffering acute renal pain, or there was vesical intolerance, he would withhold operation.

In regard to operation, the chief questions involved were drainage and treatment of the ureter. Unless there had been soiling of the wound from rupture of the kidney or persistent oozing, he refrained from drainage, and when draining, used rubber tissue for twenty-four hours for oozing. If the wound had been soiled, a split rubber tube was used for twenty-four hours or more. When there was perinephritic abscess, the kidney should be removed, if not unduly risky.

Hernia of the Female Internal Genitalia Through the Inguinal Canal.—Dr. Herbert W. Hewitt, of Detroit, Mich., said that hernia of the female internal genitalia through the inguinal canal was of relatively rare occurrence, yet it was of sufficient practical importance to justify consideration at this time. In hernia of the ovary and tube, when these were reducible and normal, they should be saved; if pathological, removal should be practised. If the hernia was irreducible the ovary should be preserved, provided it was normal and might be replaced without injury to its blood supply or without in any way weakening the herniotomy. In hernia of the uterus, between puberty and the menopause, this organ should be preserved unless there appeared to be some very good reason for its removal, while in patients at the menopause the best procedure was to remove the herniated organs. When hernia was incarcerated or strangulated, extirpation was necessary. These cases were rarely encountered.

Transplantation of Human Ovaries: Present Status and Future Possibilities.—Dr. William Seaman Bainbridge, of New York, stated that the ovarian secretion was stimulant and tonic and the sudden ablation of the ovaries in a woman before she had reached the menopause, without the substitution of an ovarian nutrient, might cause distressing mental and physical symptoms. The transplantation of ovarian tissue, either autogenous or homogenous had proved successful for both therapeutic and fertilization purposes in human beings as well as in animals. For purely therapeutic uses an implantation might be effective at any one of several sites but behind the rectus muscle where the graft would be removed from points likely to suffer traumatism, but in close proximity to the vascular and lymphatic systems, seemed the most satisfactory site. For the purposes of sterilization, where the ovaries had been removed and the uterus was intact, in a woman of childbearing age, a normal piece of ovarian tissue grafted in continuity with the Fallopian tubes or at the stump of a tube, if the tubes had been excised, might live, form follicles and ova and a pregnancy be produced from the transplanted ovary. In transplanting ovaries the closer the relationship between donor and recipient the better.

An Operation for Retrodisplacements of the Uterus.—Dr. John W. Keefe, of Providence, R. I., said that attaching the bladder to a higher position on the uterus had the effect of holding the uterus in a normal anteverted position, and of raising the anterior vaginal wall. Shortening the round ligaments by the method advocated had the advantage of retaining the original attachments of the round ligament, so that traction upon the fundus of the uterus was normally applied.

Contagious Impetigo in the Newborn.—Dr. William Mortimer Brown, of Rochester, N. Y., stated that one of the very real problems with which the administration of a maternity department had to deal was skin infections in the nursery. The susceptibility of the newly born child's skin to infection was a matter which had to be carefully considered in prescribing a standard of hygiene in the nursery. The large number of infants in one department necessitated the group method of care and economic and administrative conditions compelled the assignment of one nurse to a fairly large number of babies.

Importance of Ureteral Palpation in the Diagnosis of Abdominal Disease.—Dr. David W. Tovey, of New York, stated that normal ureters were easily palpated and it was more easy to palpate diseased ureters. Palpation of the pelvic ureters would often clear up a difficult case, the diagnosis of which seemed impossible before palpation. The nerve plexuses of the ureter anastomosed with all the other nerve plexuses of the abdominal sympathetic, so that pain from ureteral disturbance was diffuse, and might be mistaken for abdominal or pelvic disease.

Abdominal Adhesions.—Dr. Miles F. Porter, of Fort Wayne, Ind., said that adhesions which were not obstructive either to the circulation or to the lumen of hollow viscera and were not accompanied by infection were harmless. Such adhesions met with in the course of abdominal operations had better not be disturbed. Interposition of foreign substances between the viscera, either solid, liquid, semisolid or gaseous would not prevent adhesions. In the maximum conservation of tissues and general resisting powers we had the best means known today of avoiding harmful adhesions. Undue efforts to do socalled ideal surgery were to be discouraged.

Primary Sterility.—Dr. Abraham J. Rongy, of New York, stated that transuterine insufflation of the peritoneal cavity with oxygen or carbon dioxide gas, as developed by Rubin, was a very valuable aid in the diagnosis of sterility. We had no other method of examination, which so clearly demonstrated the patency of the Fallopian tubes. Once the patency of the Fallopian tubes was positively established the patient would no longer be subjected to exploratory operations on the mere suspicions that the tubes might be closed. This method of examination should be utilized in every case in which the cause of sterility was of doubtful origin. It was especially useful in patients, who had had one Fallopian tube removed because of infection or extrauterine pregnancy. By means of transuterine insufflation the patency of the tubes could be established with the least amount of traumatism to their mucous membranes. It was also employed in patients who had had plastic operations on the tubes.

Hemorrhages in the Newborn.—Dr. Lucius A. Wing, of New York, said that hemorrhages developing in the infant during birth or shortly thereafter were of greater frequency than was formerly believed. They often occurred in babies born spontaneously. Sudden or severe compression of the child's head, either by the natural forces of labor or by some obstetrical procedure, was the chief mechanical cause of intracranial lesions. Asphyxia of the infant during birth had an influence on the stability of the blood and impaired the clotting power. This rendered these infants especially susceptible to both immediate and delayed hemorrhagic lesions. Therapeutic measures to be effective in these cases should be employed early in their development.

Is Supravaginal Hysterectomy Ever Justifiable?—Dr. J. Wilson Poucher, of Poughkeepsie, N. Y., stated that he did not wish to be understood as advocating the wanton removal of the uterus or any other organs when it was not necessary. He had never observed that removal of the uterus had had any effect upon a woman's subsequent health conditions, except the complete cessation of menstruation. Removal of the ovaries or all the adnexa, if the uterus was left, did not affect menstruation, which was purely a function of the uterus. The necessity for removing an ovary should be very great.

Surgical Strategy as an Adjunct to Local Anesthesia.—Dr. Robert Emmet Farr, of Minneapolis, Minn., said that exposure and the absence of expulsive effort were the prime essentials in meeting the surgical demands in this class of cases. The abolition of the abdominal reflexes, vertical retraction, tilting of the table, combined with a negative intraabdominal pressure, the cooperation of the patient which was best obtained by solicitous care of this individual from the time he presented himself for treatment, combined with the utilization of the skill and tact of a well trained psychoanesthetist, would make it possible to perform a large amount of abdominal surgery under local anesthesia.

Surgical Treatment of Certain Puerperal Infections.—Dr. J. F. Baldwin, of Columbus, Ohio, stated that without operative intervention all of these patients died. In those rather rare cases in which the disease was practically limited to the ovarian veins, ligation of the veins above the thrombus was feasible, but the death rate, as shown by Miller, was not less than sixty per cent. Radical operation with free drainage of all the infected veins, and usually with hysterectomy, according to the results obtained in sixty-three consecutive cases, gave a death rate of a little less than thirty-two per cent.

The Defenseless Areas of the Abdomen.—Dr. George W. Crile, of Cleveland, Ohio, said that in a general way the defense of the tissues of the abdomen varied from almost one hundred per cent. in the mucosa of the intestine to almost nothing in the retroperitoneal area, where contamination slowly, but insidiously and progressively, went on to infection. In between the two lay the peritoneum, contamination of which rapidly progressed to infection, but as rapidly called into action the mechanism of defense. The adequate defense of any tissue against infection demanded an adequate nerve supply and an abundant supply of blood.

Abstracts from Current Literature

CARDIOVASCULAR DISEASE.

Endocarditis Lenta.—H. J. Starling (*Quarterly Journal of Medicine,* April, 1923) reports fifty-two cases of endocarditis lenta occurring in discharged soldiers, most of whom had been in service in France for over three years. The incidence of this disease among hospital admissions is much higher, probably two to one, for soldiers than for the civilian group during the same years, and the author believes that the physical stress of the overseas service has been a contributory cause. Previous rheumatic infection had occurred only infrequently. Starling does not think this is a determining cause, but wounds and other acute foci of infection were fairly frequent. The fact is emphasized that the disease is frequent in individuals who had previously been entirely well and of good physique, and with no history of previous illness. Positive blood cultures were obtained in only a small proportion of cases, but the diagnosis he believes may be accurately made clinically according to the criteria of Osler, Libman and others.

Quinidine in the Treatment of Auricular Fibrillation.—Archibald E. Clark-Kennedy (*Quarterly Journal of Medicine,* April, 1923) has treated forty-five unselected cases of auricular fibrillation with quinidine, and in thirty-seven (eighty-two per cent.) normal cardiac rhythm was restored. Compensation was restored as completely as possible with digitalis before quinidine was first administered. Cases of heart disease of short duration with auricular fibrillation of recent onset have reacted most successfully to quinidine. By the judicious selection of cases on the lines laid down by the author he believes therapeutic successes may be raised to a maximum, and the possibility of disaster reduced to a minimum, but the risks attending quinidine administration are pointed out.

Diagnosis and Treatment of Angina Pectoris.—Clifford Allbutt (*Lancet,* May 5, 1923) advances the following postulates: 1. Ninety per cent. of cases of angina pectoris are due to disease of the thoracic aorta, especially of its outer vestment, in which lie the sensory end organs which regulate the blood pressure. 2. The coronary arteries and myocardium have nothing to do with the pain of angina, but much to do with its mortality. 3. The death in angina pectoris is due ordinarily to vagus inhibition—that is, to the shock of the pain. In younger persons, in whom the myocardium is healthy, the heart usually survives the inhibition, so that in them, angina, as is often the case in syphilitic aorta, for example, may be a terrible, if not a fatal disease. True angina is rare in women; the socalled pseudoangina, on the other hand, is more frequent in women than in men. It seems to be a storm in the brachial plexus, intercostohumeral, Wrisberg and phrenic nerves. The angina patient is generally, but not always, pallid or pallescent; the pseudo-anginos are flushed in the face, and these patients are usually young, or not elderly, and the attacks may be determined by annoyance, the catamenial period, or other upset. The heart and pulse are not tranquil, as in angina proper, but throb rapidly, often with an irregular rhythm. Palpitation in angina proper does not occur. Between the attacks, there may be no signs of disease or degeneration; in the presence of such signs the diagnosis must be revised. The treatment recommended is that for aneurysm—absolute rest proportionate to the severity and stubbornness of the case, with due modifications of diet as may be necessary for the healing of the injured vessel.

Complete Heart Block Associated With Valvular Disturbance Without Symptoms, and Unaffected by Infections, Pregnancy, and Labor.—Walter L. Allespach and Hugh C. McDowell (*Bulletin of Buffalo General Hospital,* April, 1923) present a case of persistent, complete heart block of long standing without any symptoms referable to that condition. This is a striking illustration of the absolute comfort which is compatible with such a grave organic lesion and the withstanding all the exigencies of several infections, a pregnancy and an instrumental labor without any special cardiac disturbance. In order to eliminate the possibility of vagus augmentation, 0.002 gram of atropine was given subcutaneously twice without any effect.

Gluteal Aneurysm and Rupture Treated by Antyllus's Operation.—A. Wilfrid Adams (*Lancet,* April 7, 1923) reports a case in which a diagnosis of sarcoma or abscess was partly excluded by a sudden onset. The Hunterian and Anel operations were tried but failed. In both instances pulsation, however, was arrested temporarily. The author concludes that aneurysm of the gluteal artery should be treated by preliminary ligature of the internal iliac artery. This is in itself harmless and will control hemorrhage from the sac. The aneurysmal sac is dealt with locally according to the condition found in the buttock: 1, if the wall of the sac is ill defined, intrasacular ligature is the best; 2, if a well defined sac is present, then obliterative endoaneurysmorrhaphy is the ideal method.

Ouabaine Arnaud and Digitalis.—Oscar Ohlin (*Hygica,* July 15, 1923) reports studies on ouabaine conducted partly in Sweden but largely in Vaquez's clinic at La Pitié in Paris, the drug being widely used in France. Ouabaine contains the active principle of a strophanthus variety isolated by Arnaud and is more stable than the other strophanthus preparations and of determined toxicity. As to its indications, it is in acute dilatation of the heart, where delay is dangerous, that results are most conspicuous, as shown by rapid restoration of tonicity, raised blood pressure and increased diuresis, when given intravenously. And it is in this connection that the author comments on the efficacy of ouabaine in reactivating the heart for digitalis. Thus, in attempting to fortify by digitalis a dilated heart with complete arrhythmia, the prolonged diastole gives time for a greater influx of blood than the enfeebled heart can expel—the phenomenon of *action dissocié* of digitalis—and these are the cases where ouabaine can so restore the tone of the cardiac muscle—the diminished volume of the heart being clearly demonstrable—as to make it again responsive to digitalis. Other indications for the drug are: progressive insufficiency of left heart with rapid pulse and high blood pressure; acute dilatation of right heart in gravid women and others with mitral lesions, but never directly following digitalis; in heart insufficiency due to chronic pulmonary disease; in myocardial asthenia due to infectious diseases; in edema of various kinds, and ascites from cirrhosis hepatis. The dose for acute dilatation is 0.5 mgm. intravenously, renewing once daily for two or three days. For oral administration an alcoholic solution of one in one thousand (solubaine) is used ten to twenty drops daily for five to ten days for beginning insufficiency, while fifty to 150 drops daily are used in urgent cases. The author considers ouabaine of equal rank with digitalis as a therapeutic agent.

Familial Hypertension.—Jacob Rosenbloom (*Journal of Laboratory and Clinical Medicine,* July, 1923) presents a family tree illustrating this condition; both parents died at forty-five years from cerebral hemorrhage. Of their ten descendants, six who had reached the ages of forty-four or over had hypertension; one died from cerebral hemorrhage. Two others had high blood pressure. The two under thirty-five still had normal blood pressure, and the question is raised as to whether they will manifest hypertension between forty and forty-five. A study of the family tree suggests that heredity has produced in this group either a congenital aplasia of the arterial system, or a susceptibility to some endogenous toxic substance whose effect shows itself between the ages of forty and forty-five.

Different Forms of High Blood Pressure.—H. Kahler (*Wiener klinische Wochenschrift,* April 9, 1923) classifies the various forms of high blood pressure as follows:

A. Functional hypertensions, produced by change in the state of the contraction of the vascular musculature (increased tonus or spasm), which include, 1, those produced by central vasomotor stimulation or a change in the tonus, as follows: a; central psychic high blood pressure, which is only transient and in which it is possible that a congenital constitutional or an acquired hyperexcitability of the vascular centres plays a part and which may undergo transition into other central forms; b, central mechanical blood pressure, which is produced by increased cerebral pressure in recent apoplexies and encephalomalacias and also may occur as an exaggerated rise in other forms of high blood pressure and also in brain tumors; c, central toxic high blood pressure, which includes the bulbar hypertonia, the increased blood pressure in some uremic conditions, and also the hypertension of some patients with genuine contracted kidney; d, central lesional high blood pressure, caused by isolated sclerosis of the cerebral arteries, which is found not rarely in essential hypertonia and is the most frequent cause of cerebral hemorrhages and softenings and also in genuine contracted kidney; e, central reflex high blood pressure, which is transient in vascular crises, tabes dorsalis, and Basedow's disease and permanent in climacteric high blood pressure as well as in arteriosclerosis and in syphilitic mesoarteritis. 2. Those forms produced by peripheral vasomotor stimulation or change in the tonus include: a, the peripheral toxic high blood pressure, which is found in essential hypertonia and in congestion from high blood pressure, the latter being rare and considered as a hyperadrenalinemia because of the constantly increased blood sugar content; b, peripheral reflex high blood pressure, which occurs in uncomplicated cases of glomerulonephritis in all stages.

B. Anatomical hypertensions are produced by arteriosclerosis and are found in essential hypertonia as a result of functional (central and peripheral) hypertensions, possibly also primary, and also in the final stages of nephritis and genuine contracted kidney.

Investigations on the Immediate Effect of Heavy Exercise (Stair Running) on Some Phases of Circulation and Respiration in Normal Individuals.—Christen Lundsgaard and Eggert Möller (*Journal of Biological Chemistry,* February and March, 1923) present the first part of a study on the immediate effects of heavy exercise on different phases of the circulation and respiration in man. The oxygen and CO_2 contents of blood from a cubital vein were determined on seventeen normal subjects at rest and within one minute after running up and down a flight of stairs five times. The muscles of the arms were not used. After exercise the oxygen content of the venous blood was markedly decreased in sixteen of the individuals. The CO_2 content of the venous blood showed only small variations, being in some cases decreased after exercise, and in others increased.

The period following this exercise during which unusually low volumes for oxygen in the venous blood are obtained is of very short duration, about one to one and a half minutes. After this comes a period when the blood oxygen may be very high, almost as high as that found in arterial blood, and later on normal values are obtained. The values for carbon dioxide showed a marked decrease had taken place during the first minutes after exercise.

GYNECOLOGY.
